

Package ‘DECIPHER’

November 18, 2019

Type Package

Title Tools for curating, analyzing, and manipulating biological sequences

Version 2.14.0

Date 2019-10-15

Author Erik Wright

Maintainer Erik Wright <eswright@pitt.edu>

biocViews Clustering, Genetics, Sequencing, DataImport, Visualization, Microarray, QualityControl, qPCR, Alignment, WholeGenome, Microbiome, ImmunoOncology

Description A toolset for deciphering and managing biological sequences.

Depends R (>= 3.3.0), Biostrings (>= 2.35.12), RSQLite (>= 1.1), stats, parallel

Imports methods, DBI, S4Vectors, IRanges, XVector

LinkingTo Biostrings, S4Vectors, IRanges, XVector

License GPL-3

ByteCompile true

git_url <https://git.bioconductor.org/packages/DECIPHER>

git_branch RELEASE_3_10

DECIPHER-package	<i>Tools for curating, analyzing, and manipulating biological sequences</i>
------------------	---

Description

DECIPHER is a software toolset that can be used for deciphering and managing biological sequences efficiently using the R statistical programming language. The program is designed to be used with non-destructive workflows for importing, maintaining, analyzing, manipulating, and exporting a massive amount of sequences.

Details

Package: DECIPHER
 Type: Package
 Depends: R (>= 2.13.0), Biostrings (>= 2.35.12), RSQLite (>= 1.1), stats, parallel
 Imports: methods, DBI, S4Vectors, IRanges, XVector
 LinkingTo: Biostrings, RSQLite, S4Vectors, IRanges, XVector
 License: GPL-3
 LazyLoad: yes

Index:

AA_REDUCED	Reduced amino acid alphabets
Add2DB	Add Data to a Database
AdjustAlignment	Improve An Existing Alignment By Adjusting Gap Placements
AlignDB	Align Two Sets of Aligned Sequences in a Sequence Database
AlignProfiles	Align Two Sets of Aligned Sequences
AlignSeqs	Align a Set of Unaligned Sequences
AlignSynteny	Pairwise Aligns Syntenic Blocks
AlignTranslation	Align Sequences By Their Amino Acid Translation
AmplifyDNA	Simulate Amplification of DNA by PCR
Array2Matrix	Create a Matrix Representation of a Microarray
BrowseDB	View a Database Table in a Web Browser
BrowseSeqs	View Sequences in a Web Browser
CalculateEfficiencyArray	Predict the Hybridization Efficiency of Probe/Target Sequence Pairs
CalculateEfficiencyFISH	Predict Thermodynamic Parameters of Probe/Target Sequence Pairs
CalculateEfficiencyPCR	Predict Amplification Efficiency of Primer Sequences
Codec	Compression/Decompression of Character Vectors
ConsensusSequence	Create a Consensus Sequence
CorrectFrameshifts	Corrects Frameshift Errors In Protein Coding Sequences

CreateChimeras	Create Artificial Chimeras
DB2Seqs	Export Database Sequences to a FASTA or FASTQ File
deltaGrules	Free Energy of Hybridization of Probe/Target Quadruplets
deltaHrules	Change in Enthalpy of Hybridization of Primer/Target Quadruplets in Solution
deltaSrules	Change in Entropy of Hybridization of Primer/Target Quadruplets in Solution
DesignArray	Design a Set of DNA Microarray Probes for Detecting Sequences
DesignPrimers	Design Primers Targeting a Specific Group of Sequences
DesignProbes	Design FISH Probes Targeting a Specific Group of Sequences
DesignSignatures	Design PCR Primers for Amplifying Group-Specific Signatures
DigestDNA	Simulate Restriction Digestion of DNA
Disambiguate	Expand Ambiguities into All Permutations of a DNAStrngSet
DistanceMatrix	Calculate the Distance Between Sequences
FindChimeras	Find Chimeras in a Sequence Database
FindSynteny	Finds Synteny in a Sequence Database
FormGroups	Forms Groups By Rank
HEC_MI	Mutual Information for Protein Secondary Structure Prediction
IdClusters	Cluster Sequences By Distance or Sequence
IdConsensus	Create Consensus Sequences by Groups
IdentifyByRank	Identify By Taxonomic Rank
IdLengths	Determine the Number of Bases, Nonbases, and Width of Each Sequence
IdTaxa	Assign Sequences a Taxonomic Classification
LearnTaxa	Train a Classifier for Assigning Taxonomy
MaskAlignment	Mask Highly Variable Regions of An Alignment
MeltDNA	Simulate Melting of DNA
MIQS	MIQS Amino Acid Substitution Matrix
MODELS	Available Models of DNA Evolution
NNLS	Sequential Coordinate-wise Algorithm for the Non-negative Least Squares Problem
OrientNucleotides	Orient Nucleotide Sequences
PFASUM	PFASUM Amino Acid Substitution Matrices
PredictDBN	Predict RNA Secondary Structure in Dot-Bracket Notation
PredictHEC	Predict Protein Secondary Structure as Helix, Beta-Sheet, or Coil
Read Dendrogram	Read a Dendrogram from a Newick Formatted File
RemoveGaps	Remove Gap Characters in Sequences
RESTRICTION_ENZYMES	Common Restriction Enzyme's Cut Sites
SearchDB	Obtain Specific Sequences from a Database
Seqs2DB	Add Sequences from Text File to Database
StaggerAlignment	Produce a Staggered Alignment
Synteny-class	Synteny blocks and hits
Taxa-class	Taxa training and testing objects

TerminalChar	Determine the Number of Terminal Characters
TileSeqs	Form a Set of Tiles for Each Group of Sequences
TrainingSet_16S	Training Set for Classification of 16S rRNA Gene Sequences
TrimDNA	Trims DNA Sequences to the High Quality Region Between Patterns
WriteDendrogram	Write a Dendrogram to Newick Format

AA_REDUCED

Reduced amino acid alphabets

Description

The AA_REDUCED list contains reductions of the standard amino acid alphabet (AA_STANDARD).

Usage

AA_REDUCED

Details

Reduced amino alphabets can sometimes improve sensitivity and specificity of finding homologous matches between amino acid sequences. The first twelve AA_REDUCED alphabets were optimized for finding synteny between genomic sequences. The remaining alphabets are from a review of published amino acid alphabets (Solis, 2015).

References

str(AA_REDUCED)
AA_REDUCED[[1]]
```

Add2DB

Add Data to a Database

Description

Adds a data.frame to a database table by its row.names.

Usage

```
Add2DB(myData,  
        dbFile,  
        tblName = "Seqs",  
        clause = "",  
        verbose = TRUE)
```

Arguments

myData	Data frame containing information to be added to the dbFile.
dbFile	A SQLite connection object or a character string specifying the path to the database file.
tblName	Character string specifying the table in which to add the data.
clause	An optional character string to append to the query as part of a “where clause”.
verbose	Logical indicating whether to display each query as it is sent to the database.

Details

Data contained in myData will be added to the tblName by its respective row.names.

Value

Returns TRUE if the data was added successfully, or FALSE otherwise.

Add2DB(ids, dbConn, clause="accession like 'EU808318%')
BrowseDB(dbConn) # only 1 row effected

dbDisconnect(dbConn)
```

AdjustAlignment

Improve An Existing Alignment By Adjusting Gap Placements

Description

Makes small adjustments by shifting groups of gaps left and right to find their optimal positioning in a multiple sequence alignment.

Usage

```
AdjustAlignment(myXStringSet,
                perfectMatch = 5,
                misMatch = 0,
                gapLetter = -3,
                gapOpening = -0.1,
                gapExtension = 0,
                substitutionMatrix = NULL,
                shiftPenalty = -0.2,
                threshold = 0.1,
                weight = 1,
                processors = 1)
```

Arguments

myXStringSet	An AAStringSet, DNAStrngSet, or RNAStrngSet object of aligned sequences.
perfectMatch	Numeric giving the reward for aligning two matching nucleotides in the alignment. Only used for DNAStrngSet or RNAStrngSet inputs.
misMatch	Numeric giving the cost for aligning two mismatched nucleotides in the alignment. Only used for DNAStrngSet or RNAStrngSet inputs.
gapLetter	Numeric giving the cost for aligning gaps to letters. A lower value (more negative) encourages the overlapping of gaps across different sequences in the alignment.
gapOpening	Numeric giving the cost for opening or closing a gap in the alignment.
gapExtension	Numeric giving the cost for extending an open gap in the alignment.
substitutionMatrix	Either a substitution matrix representing the substitution scores for an alignment or the name of the amino acid substitution matrix to use in alignment. The latter may be one of the following: "BLOSUM45", "BLOSUM50", "BLOSUM62", "BLOSUM80", "BLOSUM100", "PAM30", "PAM40", "PAM70", "PAM120", "PAM250", or "MIQS". The default (NULL) will use the perfectMatch and misMatch penalties for DNA/RNA or PFASUM50 for AA.
shiftPenalty	Numeric giving the cost for every additional position that a group of gaps is shifted.
threshold	Numeric specifying the improvement in score required to permanently apply an adjustment to the alignment.
weight	A numeric vector of weights for each sequence, or a single number implying equal weights.
processors	The number of processors to use, or NULL to automatically detect and use all available processors.

Details

The process of multiple sequence alignment often results in the integration of small imperfections into the final alignment. Some of these errors are obvious by-eye, which encourages manual refinement of automatically generated alignments. However, the manual refinement process is inherently subjective and time consuming. AdjustAlignment refines an existing alignment in a process similar to that which might be applied manually, but in a repeatable and much faster fashion. This function shifts all of the gaps in an alignment to the left and right to find their optimal positioning. The optimal position is defined as the position that maximizes the alignment "score", which is determined by the input parameters. The resulting alignment will be similar to the input alignment but with many imperfections eliminated. Note that the affine gap penalties here are different from the more flexible penalties used in [AlignProfiles](#), and have been optimized independently.

Value

An XStringSet of aligned sequences.

BrowseSeqs(adjustedDNA, highlight=1)
adjustedDNA==dna # most sequences were adjusted (those marked FALSE)
```

AlignDB

Align Two Sets of Aligned Sequences in a Sequence Database

Description

Merges the two separate sequence alignments in a database. The aligned sequences must have separate identifiers in the same table or be located in different database tables.

Usage

```
AlignDB(dbFile,
        tblName = "Seqs",
        identifier = "",
        type = "DNASTringSet",
        add2tbl = "Seqs",
        batchSize = 10000,
        perfectMatch = 5,
        misMatch = 0,
        gapOpening = -13,
        gapExtension = -1,
        gapPower = -0.5,
        terminalGap = -5,
        normPower = c(1, 0),
        substitutionMatrix = NULL,
        processors = 1,
        verbose = TRUE,
        ...)
```

Arguments

<code>dbFile</code>	A SQLite connection object or a character string specifying the path to the database file.
<code>tblName</code>	Character string specifying the table(s) where the sequences are located. If two <code>tblNames</code> are provided then the sequences in both tables will be aligned.
<code>identifier</code>	Optional character string used to narrow the search results to those matching a specific identifier. If "" then all identifiers are selected. If two <code>identifiers</code> are provided then the set of sequences matching each identifier will be aligned.
<code>type</code>	The type of <code>XStringSet</code> being processed. This should be (an abbreviation of) one of "AAStringSet", "DNAStringSet", or "RNAStringSet".
<code>add2tbl</code>	Character string specifying the table name in which to add the aligned sequences.
<code>batchSize</code>	Integer specifying the number of sequences to process at a time.
<code>perfectMatch</code>	Numeric giving the reward for aligning two matching nucleotides in the alignment. Only used when <code>type</code> is <code>DNAStringSet</code> or <code>RNAStringSet</code> .
<code>misMatch</code>	Numeric giving the cost for aligning two mismatched nucleotides in the alignment. Only used when <code>type</code> is <code>DNAStringSet</code> or <code>RNAStringSet</code> .
<code>gapOpening</code>	Numeric giving the cost for opening a gap in the alignment.
<code>gapExtension</code>	Numeric giving the cost for extending an open gap in the alignment.
<code>gapPower</code>	Numeric specifying the exponent to use in the gap cost function.
<code>terminalGap</code>	Numeric giving the cost for allowing leading and trailing gaps ("- or ." characters) in the alignment. Either two numbers, the first for leading gaps and the second for trailing gaps, or a single number for both.
<code>normPower</code>	Numeric giving the exponent that controls the degree of normalization applied to scores by column occupancy. If two numerics are provided, the first controls the normalization power of terminal gaps, while the second controls that of internal gaps. A <code>normPower</code> of 0 does not normalize the scores, which results in all columns of the profiles being weighted equally, and is the optimal value for aligning fragmentary sequences. A <code>normPower</code> of 1 normalizes the score for aligning two positions by their column occupancy (1 - fraction of gaps). A <code>normPower</code> greater than 1 more strongly discourages aligning with "gappy" regions of the alignment.
<code>substitutionMatrix</code>	Either a substitution matrix representing the substitution scores for an alignment or the name of the amino acid substitution matrix to use in alignment. The latter may be one of the following: "BLOSUM45", "BLOSUM50", "BLOSUM62", "BLOSUM80", "BLOSUM100", "PAM30", "PAM40", "PAM70", "PAM120", "PAM250", or "MIQS". The default (NULL) will use the <code>perfectMatch</code> and <code>misMatch</code> penalties for DNA/RNA or <code>PFASUM50</code> for AA.
<code>processors</code>	The number of processors to use, or NULL to automatically detect and use all available processors.
<code>verbose</code>	Logical indicating whether to display progress.
<code>...</code>	Further arguments to be passed directly to Codec .

Details

Sometimes it is useful to align two large sets of sequences, where each set of sequences is already aligned but the two sets are not aligned to each other. `AlignDB` first builds a profile of each sequence

set in increments of batchSize so that the entire sequence set is not required to fit in memory. Next the two profiles are aligned using dynamic programming. Finally, the new alignment is applied to all the sequences as they are incrementally added to the add2tbl.

Two identifiers or tblNames must be provided, indicating the two sets of sequences to align. The sequences corresponding to the first identifier and tblName will be aligned to those of the second identifier or tblName. The aligned sequences are added to add2tbl under a new identifier formed from the concatenation of the two identifiers or tblNames. (See examples section below.)

Value

Returns the number of newly aligned sequences added to the database.

BrowseDB(dbConn) # note the sequences with a new identifier
dbDisconnect(dbConn)
```

AlignProfiles

*Align Two Sets of Aligned Sequences***Description**

Aligns two sets of one or more aligned sequences by first generating representative profiles, then aligning the profiles with dynamic programming, and finally merging the two aligned sequence sets.

Usage

```
AlignProfiles(pattern,
              subject,
              p.weight = 1,
              s.weight = 1,
              p.struct = NULL,
              s.struct = NULL,
              perfectMatch = 5,
              misMatch = 0,
              gapOpening = -13,
              gapExtension = -1,
              gapPower = -0.5,
              terminalGap = -5,
              restrict = c(-1000, 2, 10),
              anchor = 0.7,
              normPower = c(1, 0),
              substitutionMatrix = NULL,
              structureMatrix = NULL,
              processors = 1)
```

Arguments

pattern	An AAStringSet, DNASTringSet, or RNASTringSet object of aligned sequences to use as the pattern.
subject	A XStringSet object of aligned sequences to use as the subject. Must match the type of the pattern.
p.weight	A numeric vector of weights for each sequence in the pattern to use in generating a profile, or a single number implying equal weights.
s.weight	A numeric vector of weights for each sequence in the subject to use in generating a profile, or a single number implying equal weights.
p.struct	Either NULL (the default), a matrix, or a list of matrices with one list element per sequence in the pattern. (See details section below.)
s.struct	Either NULL (the default), a matrix, or a list of matrices with one list element per sequence in the subject. (See details section below.)
perfectMatch	Numeric giving the reward for aligning two matching nucleotides in the alignment. Only applicable for DNASTringSet or RNASTringSet inputs.
misMatch	Numeric giving the cost for aligning two mismatched nucleotides in the alignment. Only applicable for DNASTringSet or RNASTringSet inputs.
gapOpening	Numeric giving the cost for opening a gap in the alignment.

gapExtension	Numeric giving the cost for extending an open gap in the alignment.
gapPower	Numeric specifying the exponent to use in the gap cost function. (See details section below.)
terminalGap	Numeric giving the cost for allowing leading and trailing gaps ("- or ." characters) in the alignment. Either two numbers, the first for leading gaps and the second for trailing gaps, or a single number for both.
restrict	Numeric vector of length three controlling the degree of restriction around ridge lines in the dynamic programming matrix. The first element determines the span of the region around a ridge that is considered during alignment. The default (-1000) will align most inputs that can reasonably be globally aligned without any loss in accuracy. Input sequences with high similarity could be more restricted (e.g., -500), whereas a pattern and subject with little overlap could be less restricted (e.g., -10000). The second element sets the minimum slope to either side of a ridge that is required to allow restriction at any point. The third element sets the minimum duration of the ridge required to begin restricting the matrix around the ridge. The duration of the ridge is defined as the number of consecutive positions meeting the first two conditions for restriction. (See details section below.)
anchor	Numeric giving the fraction of sequences with identical k-mers required to become an anchor point, or NA to not use anchors. Alternatively, a matrix specifying anchor regions. (See details section below.)
normPower	Numeric giving the exponent that controls the degree of normalization applied to scores by column occupancy. If two numerics are provided, the first controls the normalization power of terminal gaps, while the second controls that of internal gaps. A normPower of 0 does not normalize the scores, which results in all columns of the profiles being weighted equally, and is the optimal value for aligning fragmentary sequences. A normPower of 1 normalizes the score for aligning two positions by their column occupancy (1 - fraction of gaps). A normPower greater than 1 more strongly discourages aligning with "gappy" regions of the alignment. (See details section below.)
substitutionMatrix	Either a substitution matrix representing the substitution scores for an alignment or the name of the amino acid substitution matrix to use in alignment. The latter may be one of the following: "BLOSUM45", "BLOSUM50", "BLOSUM62", "BLOSUM80", "BLOSUM100", "PAM30", "PAM40", "PAM70", "PAM120", "PAM250", or "MIQS". The default (NULL) will use the perfectMatch and misMatch penalties for DNA/RNA or PFASUM50 for AA. (See examples section below.)
structureMatrix	A structure matrix if p.struct and s.struct are supplied, or NULL otherwise.
processors	The number of processors to use, or NULL to automatically detect and use all available processors.

Details

Profiles are aligned using dynamic programming, a variation of the Needleman-Wunsch algorithm for global alignment. The dynamic programming method requires order $N \times M$ time and memory space where N and M are the width of the pattern and subject. This method works by filling in a matrix of the possible "alignment space" by considering all matches, insertions, and deletions between two sequence profiles. The highest scoring alignment is then used to add gaps to each of the input sequence sets.

Heuristics can be useful to improve performance on long input sequences. The `restrict` parameter can be used to dynamically constrain the possible “alignment space” to only paths that will likely include the final alignment, which in the best case can improve the speed from quadratic time to nearly linear time. The degree of restriction is important, and the default value of `restrict` is reasonable in the vast majority of cases. It is also possible to prevent restriction by setting `restrict` to such extreme values that these requirements will never be met (e.g., `c(-1e10, 1e10, 1e10)`).

The argument `anchor` can be used to split the global alignment into multiple sub-alignments. This can greatly decrease the memory requirement for long sequences when appropriate anchor points can be found. Anchors are 15-mer (for DNA/RNA) or 7-mer (for AA) subsequences that are shared between at least anchor fraction of pattern(s) and subject(s). Anchored ranges are extended along the length of each sequence in a manner designed to split the alignment into sub-alignments that can be separately solved. For most input sequences, the default anchoring has no effect on accuracy, but anchoring can be disabled by setting `anchor=NA`.

Alternatively, `anchor` can be a matrix with 4 rows and one column per anchor. The first two rows correspond to the anchor start and end positions in the pattern sequence(s), and the second two rows are the equivalent anchor region in the subject sequence(s). Anchors specified in this manner must be strictly increasing (non-overlapping) in both sequences, and have an anchor width of at least two positions. Note that the anchors do not have to be equal length, in which case the anchor regions will also be aligned. Manually splitting the alignment into more subtasks can sometimes make it more efficient, but typically automatic anchoring is effective.

The argument `normPower` determines how the distribution of information is treated during alignment. Higher values of `normPower` encourage alignment between columns with higher occupancy (1 - fraction of gaps), and de-emphasize the alignment of columns containing many gaps. A `normPower` of 0 will treat all columns equally regardless of occupancy, which can be useful when the pattern or subject contain many incomplete (fragment) sequences. For example, `normPower` should be set to 0 when aligning many short reads to a longer reference sequence.

The arguments `p.struct` and `s.struct` may be used to provide secondary structure probabilities in the form of a list containing matrices or a single matrix. If the input is a list, then each list element must contain a matrix with dimensions $q \times w$, where q is the number of possible secondary structure states, and w is the width of the unaligned pattern sequence. Values in each matrix represent the probability of the given state at that position in the sequence. Alternatively, a single matrix can be used as input if w is the width of the entire pattern or subject alignment. A `structureMatrix` must be supplied along with the structures. The functions `PredictHEC` and `PredictDBN` can be used to predict secondary structure probabilities in the format required by `AlignProfiles` (for amino acid and RNA sequences, respectively).

The gap cost function is based on the observation that gap lengths are best approximated by a Zipfian distribution (Chang & Benner, 2004). The cost of inserting a gap of length L is equal to: $\text{gapOpening} + \text{gapExtension} \times \sum(\text{seq_len}(L-1)^{\text{gapPower}})$ when $L > 1$, and gapOpen when $L = 1$. This function effectively penalizes shorter gaps significantly more than longer gaps when $\text{gapPower} < 0$, and is equivalent to the affine gap penalty when gapPower is 0.

Value

An `XStringSet` of aligned sequences.

AlignSeqs

Align a Set of Unaligned Sequences

Description

Performs profile-to-profile alignment of multiple unaligned sequences following a guide tree.

Usage

```
AlignSeqs(myXStringSet,
          guideTree = NULL,
          iterations = 2,
          refinements = 1,
          gapOpening = c(-18, -16),
          gapExtension = c(-2, -1),
          useStructures = TRUE,
          structures = NULL,
          FUN = AdjustAlignment,
          levels = c(0.9, 0.7, 0.7, 0.4, 10, 5, 5, 2),
          alphabet = AA_REDUCE[["1"]],
          processors = 1,
          verbose = TRUE,
          ...)
```

Arguments

<code>myXStringSet</code>	An AStringSet, DNAStrngSet, or RNAStrngSet object of unaligned sequences.
<code>guideTree</code>	Either NULL or a dendrogram giving the ordered tree structure in which to align profiles. If NULL then a guide tree will be automatically constructed based on the order of shared k-mers.
<code>iterations</code>	Number of iteration steps to perform. During each iteration step the guide tree is regenerated based on the alignment and the sequences are realigned.
<code>refinements</code>	Number of refinement steps to perform. During each refinement step groups of sequences are realigned to rest of the sequences, and the best of these two alignments (before and after realignment) is kept.
<code>gapOpening</code>	Single numeric giving the cost for opening a gap in the alignment, or two numbers giving the minimum and maximum costs. In the latter case the cost will be varied depending upon whether the groups of sequences being aligned are nearly identical or maximally distant.
<code>gapExtension</code>	Single numeric giving the cost for extending an open gap in the alignment, or two numbers giving the minimum and maximum costs. In the latter case the cost will be varied depending upon whether the groups of sequences being aligned are nearly identical or maximally distant.
<code>useStructures</code>	Logical indicating whether to use secondary structure predictions during alignment. If TRUE (the default), secondary structure probabilities will be automatically calculated for amino acid and RNA sequences if they are not provided (i.e., when structures is NULL).
<code>structures</code>	Either a list of secondary structure probabilities matching the structureMatrix, such as that output by PredictHEC or PredictDBN, or NULL to generate the structures automatically. Only applicable if myXStringSet is an AStringSet or RNAStrngSet.
<code>FUN</code>	A function to be applied after each profile-to-profile alignment. (See details section below.)
<code>levels</code>	Numeric with eight elements specifying the levels at which to trigger events. (See details section below.)

alphabet	Character vector of amino acid groupings used to reduce the 20 standard amino acids into smaller groups. Alphabet reduction helps to find more distant homologies between sequences. A non-reduced amino acid alphabet can be used by setting alphabet equal to AA_STANDARD. Only applicable if myXStringSet is an AAStringSet.
processors	The number of processors to use, or NULL to automatically detect and use all available processors.
verbose	Logical indicating whether to display progress.
...	Further arguments to be passed directly to AlignProfiles , including perfectMatch, misMatch, gapPower, terminalGap, restrict, anchor, normPower, substitutionMatrix, and structureMatrix.

Details

The profile-to-profile method aligns a sequence set by merging profiles along a guide tree until all the input sequences are aligned. This process has three main steps: (1) If `guideTree=NULL`, an initial single-linkage guide tree is constructed based on a distance matrix of shared k-mers. Alternatively, a dendrogram can be provided as the initial `guideTree`. (2) If `iterations` is greater than zero, then a UPGMA guide tree is built based on the initial alignment and the sequences are re-aligned along this tree. This process repeated `iterations` times or until convergence. (3) If `refinements` is greater than zero, then subsets of the alignment are re-aligned to the remainder of the alignment. This process generates two alignments, the best of which is chosen based on its sum-of-pairs score. This refinement process is repeated `refinements` times, or until convergence.

The purpose of `levels` is to speed-up the alignment process by not running time consuming processes when they are unlikely to change the outcome. The first four `levels` control when `refinements` occur and the function `FUN` is run on the alignment. The default `levels` specify that these events should happen when above 0.9 (AA; `levels[1]`) or 0.7 (DNA/RNA; `levels[3]`) average dissimilarity on the initial tree, when above 0.7 (AA; `levels[2]`) or 0.4 (DNA/RNA; `levels[4]`) average dissimilarity on the iterative tree(s), and after every tenth improvement made during refinement. The sixth element of `levels` (`levels[6]`) prevents `FUN` from being applied at any point to less than 5 sequences.

The `FUN` function is always applied just before returning the alignment so long as there are at least `levels[6]` sequences. The default `FUN` is `AdjustAlignment`, but `FUN` can be any function that takes in an `XStringSet` as its first argument, as well as `weights`, `processors`, and `substitutionMatrix` as optional arguments. For example, the default `FUN` could be altered to not perform any changes by setting it equal to `function(x, ...) return(x)`, where `x` is an `XStringSet`.

Secondary structures are automatically computed for amino acid and RNA sequences unless `structures` are provided or `useStructures` is `FALSE`. The default `structureMatrix` is used unless an alternative is provided. For RNA sequences, secondary structures are only computed when the total length of the initial guide tree is at least 5 (`levels[7]`) or the length of subsequent trees is at least 2 (`levels[8]`).

Value

An `XStringSet` of aligned sequences.

AlignSynteny

Pairwise Aligns Syntenic Blocks

Description

Performs pairwise alignment of all blocks of synteny between sets of sequences.

Usage

```
AlignSynteny(synteny,
             dbFile,
             tblName = "Seqs",
             identifier = "",
             processors = 1,
             verbose = TRUE,
             ...)
```

Arguments

synteny	An object of class "Synteny".
dbFile	A SQLite connection object or a character string specifying the path to the database file.
tblName	Character string specifying the table where the sequences are located that were used to create the object synteny.
identifier	Optional character string used to narrow the search results to those matching a specific identifier, or an integer sequence corresponding to indices of rownames(synteny). If "" (the default), then all identifiers are selected from synteny.
processors	The number of processors to use, or NULL to automatically detect and use all available processors.
verbose	Logical indicating whether to display progress.
...	Further arguments to be passed directly to AlignProfiles , including perfectMatch, misMatch, gapPower, terminalGap, restrict, normPower, and substitutionMatrix.

Details

AlignSynteny will extract all sequence regions belonging to syntenic blocks in synteny, and perform pairwise alignment with AlignProfiles. Hits are used to anchor the alignment such that only the regions between anchors are aligned.

Value

A list with elements for each pair of identifiers in synteny. Each list element contains a DNAStrngSetList one pairwise alignment per syntenic block.

unlist(DNA[[2]]) # a DNAStrngSet of synteny between H9N2 & H2N2
```

AlignTranslation

Align Sequences By Their Amino Acid Translation

Description

Performs alignment of a set of DNA or RNA sequences by aligning their corresponding amino acid sequences.

Usage

```
AlignTranslation(myXStringSet,
                 sense = "+",
                 direction = "5' to 3'",
                 readingFrame = NA,
                 type = class(myXStringSet),
                 geneticCode = GENETIC_CODE,
                 ...)
```

Arguments

myXStringSet	A DNASTringSet or RNASTringSet object of unaligned sequences.
sense	Single character specifying sense of the input sequences, either the positive ("+") coding strand or negative ("-") non-coding strand.
direction	Direction of the input sequences, either "5' to 3'" or "3' to 5'".
readingFrame	Numeric vector giving a single reading frame for all of the sequences, or an individual reading frame for each sequence in myXStringSet. The readingFrame can be either 1, 2, 3 to begin translating on the first, second, and third nucleotide position, or NA (the default) to guess the reading frame. (See details section below.)
type	Character string indicating the type of output desired. This should be (an abbreviation of) one of "DNASTringSet", "RNASTringSet", "AAStringSet", or "both". (See value section below.)
geneticCode	Either a character vector giving the genetic code in the same format as GENETIC_CODE (the default), or a list containing one genetic code for each sequence in myXStringSet.
...	Further arguments to be passed directly to AlignSeqs , including gapOpening, gapExtension, gapPower, terminalGap, restrict, anchor, normPower, substitutionMatrix, structureMatrix, alphabet, guideTree, iterations, refinements, useStructures, structures, FUN, and levels.

Details

Alignment of proteins is often more accurate than alignment of their coding nucleic acid sequences. This function aligns the input nucleic acid sequences via aligning their translated amino acid sequences. First, the input sequences are translated according to the specified sense, direction, and readingFrame. The resulting amino acid sequences are aligned using [AlignSeqs](#), and this alignment is (conceptually) reverse translated into the original sequence type, sense, and direction. Not only is alignment of protein sequences generally more accurate, but aligning translations will ensure that the reading frame is maintained in the nucleotide sequences.

If the readingFrame is NA (the default) then an attempt is made to guess the reading frame of each sequence based on the number of stop codons in the translated amino acids. For each sequence, the first reading frame will be chosen (either 1, 2, or 3) without stop codons, except in the final position. If the number of stop codons is inconclusive for a sequence then the reading frame will default to 1. The entire length of each sequence is translated in spite of any stop codons identified. Note that this method is only constructive in circumstances where there is a substantially long coding sequence with at most a single stop codon expected in the final position, and therefore it is preferable to specify the reading frame of each sequence if it is known.

Value

An XStringSet of the class specified by type, or a list of two components (nucleotides and amino acids) if type is "both". Note that incomplete starting and ending codons will be translated into the mask character ("+") if the result includes an AAStringSet.

AmplifyDNA

Simulate Amplification of DNA by PCR

Description

Predicts the amplification efficiency of theoretical PCR products (amplicons) given one or more primer sequences.

Usage

```
AmplifyDNA(primers,
            myDNAStringSet,
            maxProductSize,
            annealingTemp,
            P,
```

```

ions = 0.2,
includePrimers=TRUE,
minEfficiency = 0.001,
...)
```

Arguments

<code>primers</code>	A DNASTringSet object or character vector with one or more unaligned primer sequences in 5' to 3' orientation.
<code>myDNASTringSet</code>	A DNASTringSet object or character vector with unaligned template DNA sequences in 5' to 3' orientation.
<code>maxProductSize</code>	Integer specifying the maximum length of PCR products (amplicons) in nucleotides.
<code>annealingTemp</code>	Numeric specifying the annealing temperature used in the PCR reaction.
<code>P</code>	Numeric giving the molar concentration of primers in the reaction.
<code>ions</code>	Numeric giving the molar sodium equivalent ionic concentration. Values may range between 0.01M and 1M.
<code>includePrimers</code>	Logical indicating whether to include the primer sequences in the theoretical PCR products. (See details section below.)
<code>minEfficiency</code>	Numeric giving the minimum amplification efficiency of PCR products to include in the output (default 0.1%). (See details section below.)
<code>...</code>	Additional arguments to be passed directly to CalculateEfficiencyPCR , including <code>batchSize</code> , <code>taqEfficiency</code> , <code>maxDistance</code> , <code>maxGaps</code> , and <code>processors</code> .

Details

Exponential amplification in PCR requires the annealing and elongation of two primers from target sites on opposing strands of the template DNA. If the template DNA sequence (e.g., chromosome) is known then predictions of theoretical amplicons can be obtained from in silico simulations of amplification. AmplifyDNA first searches for primer target sites on the template DNA, and then calculates an amplification efficiency from each target site using [CalculateEfficiencyPCR](#). Ambiguity codes (IUPAC_CODE_MAP) are supported in the primers, but not in myDNASTringSet to prevent trivial matches (e.g., runs of N's).

If `taqEfficiency` is TRUE (the default), the amplification efficiency of each primer is defined as the product of hybridization efficiency and elongation efficiency. Amplification efficiency must be at least `minEfficiency` for a primer to be amplified in silico. Overall amplification efficiency of the PCR product is then calculated as the geometric mean of the two (i.e., forward and reverse) primers' efficiencies. Finally, amplicons are generated if the two primers are within `maxProductSize` nucleotides downstream of each other.

Potential PCR products are returned, either with or without including the primer sequences in the amplicon. The default (`includePrimers=TRUE`) is to incorporate the primer sequences as would normally occur during amplification. The alternative is to return the complete template sequence including the target sites, which may not exactly match the primer sequences. Note that amplicons may be duplicated when different input primers can amplify the same region of DNA.

Value

A DNASTringSet object containing potential PCR products, sorted from highest-to-lowest amplification efficiency. The sequences are named by their predicted amplification efficiency followed by the index of each primer in myDNASTringSet. (See examples section below.)

Note

The program OligoArrayAux (<http://mfold.rna.albany.edu/?q=DINAMelt/OligoArrayAux>) must be installed in a location accessible by the system. For example, the following code should print the installed OligoArrayAux version when executed from the R console:

```
system("hybrid-min -V")
```

## Not run: AmplifyDNA(primer2, yeastSEQCHR1, annealingTemp=55, P=4e-7, maxProductSize=500)

# perform a multiplex PCR amplification with multiple primers:
primers <- c(primer1, primer2)
## Not run: AmplifyDNA(primers, yeastSEQCHR1, annealingTemp=55, P=4e-7, maxProductSize=500)
```

Array2Matrix

Create a Matrix Representation of a Microarray

Description

Converts the output of DesignArray into the sparse matrix format used by NNLS.

Usage

```
Array2Matrix(probes,
              verbose = TRUE)
```

Arguments

probes	A set of microarray probes in the format output by DesignArray.
verbose	Logical indicating whether to display progress.

Details

A microarray can be represented by a matrix of hybridization efficiencies, where the rows represent each of the probes and the columns represent each the possible templates. This matrix is sparse since microarray probes are designed to only target a small subset of the possible templates.

Value

A list specifying the hybridization efficiency of each probe to its potential templates.

i	Element's row index in the sparse matrix.
j	Element's column index in the sparse matrix.
x	Non-zero elements' values representing hybridization efficiencies.
dimnames	A list of two components: the names of each probe, and the names of each template.

```

BrowseDB*View a Database Table in a Web Browser*

Description

Opens an html file in a web browser to show the contents of a table in a database.

Usage

```
BrowseDB(dbFile,  
         htmlFile = paste(tempdir(), "/db.html", sep = ""),  
         openURL = interactive(),  
         tblName = "Seqs",  
         identifier = "",  
         limit = -1,  
         orderBy = "row_names",  
         maxChars = 50,  
         clause="")
```

Arguments

<code>dbFile</code>	A SQLite connection object or a character string specifying the path to the database file.
<code>htmlFile</code>	Character string giving the location where the html file should be written.
<code>openURL</code>	Logical indicating whether the <code>htmlFile</code> should be opened in a web browser.
<code>tblName</code>	Character string specifying the table to view.
<code>identifier</code>	Optional character string used to narrow the search results to those matching a specific identifier. If "" then all identifiers are selected.
<code>limit</code>	Number of results to display. The default (-1) does not limit the number of results.
<code>orderBy</code>	Character string giving the column name for sorting the results. Defaults to the order of entries in the database. Optionally can be followed by "ASC" or "DESC" to specify ascending (the default) or descending order.
<code>maxChars</code>	Maximum number of characters to display in each column.
<code>clause</code>	An optional character string to append to the query as part of a "where clause".

Value

Creates an html table containing all the fields of the database table and (if `openURL` is TRUE) opens it in the web browser for viewing.

Returns `htmlFile` if the html file was written successfully.

Note

If viewing a table containing sequences, the sequences are purposefully not shown in the output.

```

BrowseSeqs

View Sequences in a Web Browser

Description

Opens an html file in a web browser to show the sequences in an XStringSet.

Usage

```
BrowseSeqs(myXStringSet,
            htmlFile = paste(tempdir(), "/myXStringSet.html", sep = ""),
            openURL = interactive(),
            colorPatterns = TRUE,
            highlight = NA,
            patterns = c("-", alphabet(myXStringSet, baseOnly=TRUE)),
            colors = substring(rainbow(length(patterns),
                                      v=0.8, start=0.9, end=0.7), 1, 7),
            colWidth = Inf,
            ...)
```

Arguments

<code>myXStringSet</code>	A XStringSet object of sequences.
<code>htmlFile</code>	Character string giving the location where the html file should be written.
<code>openURL</code>	Logical indicating whether the htmlFile should be opened in a web browser.
<code>colorPatterns</code>	Logical specifying whether to color matched patterns, or an integer vector providing pairs of start and stop boundaries for coloring.
<code>highlight</code>	Numeric specifying which sequence in the set to use for comparison or NA to color all sequences (default). If highlight is 0 then positions differing from the consensus sequence are highlighted.
<code>patterns</code>	Either an AAStrngSet, DNAStrngSet, or RNAStrngSet object, a character vector containing regular expressions, a list of numeric matrices, or NULL. (See details section below.)
<code>colors</code>	Character vector providing the color for each of the matched patterns. Typically a character vector with elements of 7 characters: “#” followed by the red, blue, green values in hexadecimal (after rescaling to 0 ... 255). Ignored when patterns is a list of matrices.

<code>colWidth</code>	Integer giving the maximum number of nucleotides wide the display can be before starting a new page. Must be a multiple of 20 (e.g., 100), or <code>Inf</code> (the default) to display all the sequences in one set of rows.
<code>...</code>	Additional arguments to adjust the appearance of the consensus sequence at the base of the display. Passed directly to <code>ConsensusSequence</code> for an <code>AAStringSet</code> , <code>DNAStringSet</code> , or <code>RNAStringSet</code> , or to <code>consensusString</code> for a <code>BStringSet</code> .

Details

`BrowseSeqs` converts an `XStringSet` into html format for viewing in a web browser. The sequences are colored in accordance with the patterns that are provided, or left uncolored if `colorPatterns` is `FALSE` or `patterns` is `NULL`. Character or `XStringSet` patterns are matched as regular expressions and colored according to colors. If `patterns` is a list of matrices, then it must contain one element per sequence. Each matrix is interpreted as providing the fraction red, blue, and green for each letter in the sequence. Thus, `colors` is ignored when `patterns` is a list. (See examples section below.)

Patterns are not matched across column breaks, so multi-character patterns should be carefully considered when `colWidth` is less than the maximum sequence length. Patterns are matched sequentially in the order provided, so it is feasible to use nested patterns such as `c("ACCTG", "CC")`. In this case the "CC" could be colored differently inside the previously colored "ACCTG". Note that patterns overlapping the boundaries of a previously matched pattern will not be matched. For example, "ACCTG" would not be matched if `patterns=c("CC", "ACCTG")`.

Some web browsers cannot quickly display a large amount colored text, so it is recommended to use `colorPatterns = FALSE` or to highlight a sequence when viewing a large `XStringSet`. Highlighting will only show all of the characters in the highlighted sequence, and convert all matching positions in the other sequences into dots without color. Also, note that some web browsers display small shifts between fixed-width characters that may become noticeable as color offsets between the ends of long sequences.

Value

Creates an html file containing sequence data and (if `openURL` is `TRUE`) opens it in a web browser for viewing. The layout has the sequence name on the left, position legend on the top, cumulative number of nucleotides on the right, and consensus sequence on the bottom.

Returns `htmlFile` if the html file was written successfully.

Note

Some web browsers do not display colored characters with equal widths. If positions do not align across sequences then try opening the `htmlFile` with a different web browser.

CalculateEfficiencyArray

Predict the Hybridization Efficiency of Probe/Target Sequence Pairs

Description

Calculates the Gibbs free energy and hybridization efficiency of probe/target pairs at varying concentrations of the denaturant formamide.

Usage

```

CalculateEfficiencyArray(probe,
                        target,
                        FA = 0,
                        dGini = 1.96,
                        Po = 10^-2.0021,
                        m = 0.1731,
                        temp = 42,
                        deltaGrules = NULL)

```

Arguments

probe	A DNASTringSet object or character vector with pairwise-aligned probe sequences in 5' to 3' orientation.
target	A DNASTringSet object or character vector with pairwise-aligned target sequences in 5' to 3' orientation.
FA	A vector of one or more formamide concentrations (as percent v/v).

dGini	The initiation free energy. The default is 1.96 [kcal/mol].
Po	The effective probe concentration.
m	The m-value defining the linear relationship of denaturation in the presence of formamide.
temp	Equilibrium temperature in degrees Celsius.
deltaGrules	Free energy rules for all possible base pairings in quadruplets. If NULL, defaults to the parameters obtained using NimbleGen microarrays and a Linear Free Energy Model developed by Yilmaz <i>et al.</i>

Details

This function calculates the free energy and hybridization efficiency (HE) for a given formamide concentration ([FA]) using the linear free energy model given by:

$$HE = Po * exp[-(dG_0 + m * FA)/RT] / (1 + Po * exp[-(dG_0 + m * FA)/RT])$$

The probe and target input sequences must be aligned in pairs, such that the first probe is aligned to the first target, second-to-second, and so on. Ambiguity codes in the IUPAC_CODE_MAP are accepted in probe and target sequences. Any ambiguities will default to perfect match pairings by inheriting the nucleotide in the same position on the opposite sequence whenever possible. If the ambiguity results in a mismatch then “T”, “G”, “C”, and “A” are substituted, in that order. For example, if a probe nucleotide is “S” (“C” or “G”) then it will be considered a “C” if the target nucleotide in the same position is a “C”, otherwise the ambiguity will be interpreted as a “G”.

If deltaGrules is NULL then the rules defined in data(deltaGrules) will be used. Note that deltaGrules of the same format may be customized for any application and specified as an input.

Value

A matrix with the predicted Gibbs free energy (dG) and hybridization efficiency (HE) at each concentration of formamide ([FA]).

 CalculateEfficiencyFISH

Predict Thermodynamic Parameters of Probe/Target Sequence Pairs

Description

Calculates the Gibbs free energy, formamide melt point, and hybridization efficiency of probe/target (DNA/RNA) pairs.

Usage

```
CalculateEfficiencyFISH(probe,
                        target,
                        temp,
                        P,
                        ions,
                        FA,
                        batchSize = 1000)
```

Arguments

probe	A DNASTringSet object or character vector with unaligned probe sequences in 5' to 3' orientation.
target	A DNASTringSet object, RNASTringSet, or character vector with unaligned target or non-target sequences in 5' to 3' orientation. The DNA base Thymine will be treated the same as Uracil.
temp	Numeric specifying the hybridization temperature, typically 46 degrees Celsius.
P	Numeric giving the molar concentration of probes during hybridization.
ions	Numeric giving the molar sodium equivalent ionic concentration. Values may range between 0.01M and 1M. Note that salt correction is not available for thermodynamic rules of RNA/RNA interactions, which were determined at 1 molar concentration.
FA	Numeric concentration (as percent v/v) of the denaturant formamide in the hybridization buffer.
batchSize	Integer specifying the number of probes to simulate hybridization per batch. See the Description section below.

Details

Hybridization of pairwise probe/target (DNA/RNA) pairs is simulated *in silico*. Gibbs free energies are obtained from system calls to OligoArrayAux, which must be properly installed (see the Notes section below). Probe/target pairs are sent to OligoArrayAux in batches of batchSize, which prevents systems calls from being too many characters. Note that OligoArrayAux does not support degeneracy codes (non-base letters), although they are accepted without error. Any sequences with ambiguity should be expanded into multiple permutations with [Disambiguate](#) before input.

Value

A matrix of predicted hybridization efficiency (HybEff), formamide melt point (FAm), and free energy (ddG1 and dG1) for each probe/target pair of sequences.

Note

The program OligoArrayAux (<http://mfold.rna.albany.edu/?q=DINAMelt/OligoArrayAux>) must be installed in a location accessible by the system. For example, the following code should print the installed OligoArrayAux version when executed from the R console:

```
system("hybrid-min -V")
```

```

CalculateEfficiencyPCR

Predict Amplification Efficiency of Primer Sequences

Description

Calculates the amplification efficiency of primers from their hybridization efficiency and elongation efficiency at the target site.

Usage

```
CalculateEfficiencyPCR(primer,
                      target,
                      temp,
                      P,
                      ions,
                      batchSize = 1000,
                      taqEfficiency = TRUE,
                      maxDistance = 0.4,
                      maxGaps = 2,
                      processors = 1)
```

Arguments

primer	A DNAStrngSet object or character vector with unaligned primer sequences in 5' to 3' orientation.
target	A DNAStrngSet object or character vector with unaligned target or non-target sequences in 5' to 3' orientation.
temp	Numeric specifying the annealing temperature used in the PCR reaction.
P	Numeric giving the molar concentration of primers in the reaction.
ions	Numeric giving the molar sodium equivalent ionic concentration. Values may range between 0.01M and 1M.
batchSize	Integer specifying the number of primers to simulate hybridization per batch. See the Description section below.
taqEfficiency	Logical determining whether to make use of elongation efficiency and maxDistance to increase predictive accuracy for <i>Taq</i> DNA Polymerase amplifying primers with mismatches near the 3' terminus. Note that this should be set to FALSE if using a high-fidelity polymerase with 3' to 5' exonuclease activity.
maxDistance	Numeric specifying the maximal fraction of mismatched base pairings on a rolling basis beginning from the 3' end of the primer. Only used if taqEfficiency is TRUE.
maxGaps	Integer specifying the maximum number of insertions or deletions (indels) in the primer/target alignment. Only used if taqEfficiency is TRUE.
processors	The number of processors to use, or NULL to automatically detect and use all available processors.

Details

Amplification of pairwise primer/target pairs is simulated *in silico*. A complex model of hybridization is employed that takes into account the side reactions resulting from probe-folding, target-folding, and primer-dimer formation. The resulting hybridization efficiency is multiplied by the elongation efficiency to predict the overall efficiency of amplification.

Free energy is obtained from system calls to OligoArrayAux, which must be properly installed (see the Notes section below). Primer/target pairs are sent to OligoArrayAux in batches of batchSize, which prevents systems calls from being too many characters. Note that OligoArrayAux does not support degeneracy codes (non-base letters), although they are accepted without error. Any sequences with ambiguity should be expanded into multiple permutations with [Disambiguate](#) before input.

Value

A vector of predicted efficiencies for amplifying each primer/target pair of sequences.

Note

The program OligoArrayAux (<http://mfold.rna.albany.edu/?q=DINAMelt/OligoArrayAux>) must be installed in a location accessible by the system. For example, the following code should print the installed OligoArrayAux version when executed from the R console:

```
system("hybrid-min -V")
```

Codec

Compression/Decompression of Character Vectors

Description

Compresses character vectors into raw vectors, or decompresses raw vectors into character vectors using a variety of codecs.

Usage

```
Codec(x,
      compression,
      compressRepeats = FALSE,
      processors = 1)
```

Arguments

<code>x</code>	Either a character vector to be compressed, or a list of raw vectors to be decompressed.
<code>compression</code>	The type of compression algorithm to use when <code>x</code> is a character vector. This should be (an unambiguous abbreviation of) one of "nbit" (for nucleotides), "qbit" (for quality scores), "gzip", "bzip2", or "xz". If <code>compression</code> is "nbit" or "qbit" then a second method can be provided for cases when <code>x</code> is incompressible. Decompression type is determined automatically. (See details section below.)
<code>compressRepeats</code>	Logical specifying whether to compress exact repeats and reverse complement repeats in a character vector input (<code>x</code>). Only applicable when <code>compression</code> is "nbit". Repeat compression in long DNA sequences generally increases compression by about 2% while requiring three-fold more compression time.
<code>processors</code>	The number of processors to use, or NULL to automatically detect and use all available processors.

Details

Codec can be used to compress/decompress character vectors using different algorithms. The "nbit" and "qbit" methods are tailored specifically to nucleotides and quality scores, respectively. These two methods will store the data as plain text ("ASCII" format) when it is incompressible. In such cases, a second compression method can be given to use in lieu of plain text. For example `compression = c("nbit", "gzip")` will use "gzip" compression when "nbit" compression is inappropriate.

When performing the reverse operation, decompression, the type of compression is automatically detected based on the unique signature ("magic number") added by each compression algorithm.

Value

If `x` is a character vector to be compressed, the output is a list with one element containing a raw vector per character string. If `x` is a list of raw vectors to be decompressed, then the output is a character vector with one string per list element.

Author(s)

Erik Wright <eswright@pitt.edu>

Examples

```
fas <- system.file("extdata", "Bacteria_175seqs.fas", package="DECIPHER")
dna <- as.character(readDNASTringSet(fas)) # aligned sequences
object.size(dna)

# compression
system.time(x <- Codec(dna, compression="nbit"))
object.size(x)/sum(nchar(dna)) # bytes per position

system.time(g <- Codec(dna, compression="gzip"))
object.size(g)/sum(nchar(dna)) # bytes per position

# decompression
system.time(y <- Codec(x))
stopifnot(dna==y)

system.time(z <- Codec(g))
stopifnot(dna==z)
```

Description

Forms a consensus sequence representing a set of sequences.

Usage

```
ConsensusSequence(myXStringSet,
                  threshold = 0.05,
                  ambiguity = TRUE,
                  noConsensusChar = "+",
                  minInformation = 1 - threshold,
                  ignoreNonBases = FALSE,
                  includeTerminalGaps = FALSE)
```

Arguments

<code>myXStringSet</code>	An <code>AAStringSet</code> , <code>DNAStrngSet</code> , or <code>RNAStringSet</code> object of aligned sequences.
<code>threshold</code>	Numeric specifying that less than <code>threshold</code> fraction of sequence information can be lost at any position of the consensus sequence.
<code>ambiguity</code>	Logical specifying whether to consider ambiguity as split between their respective nucleotides. Degeneracy codes are specified in the <code>IUPAC_CODE_MAP</code> .
<code>noConsensusChar</code>	Single character from the sequence's alphabet giving the base to use when there is no consensus in a position.
<code>minInformation</code>	Minimum fraction of information required to form consensus in each position.
<code>ignoreNonBases</code>	Logical specifying whether to count gap ("-"), mask ("+"), and unknown (".") characters towards the consensus.
<code>includeTerminalGaps</code>	Logical specifying whether or not to include terminal gaps ("-") or (".") characters on each end of the sequence) into the formation of consensus.

Details

`ConsensusSequence` removes the least frequent characters at each position, so long as they represent less than `threshold` fraction of the sequences in total. If necessary, `ConsensusSequence` represents the remaining characters using a degeneracy code from the `IUPAC_CODE_MAP`. Degeneracy codes are always used in cases where multiple characters are equally abundant.

Two key parameters control the degree of consensus: `threshold` and `minInformation`. The default `threshold` (0.05) means that at less than 5% of sequences will not be represented by the consensus sequence at any given position. The default `minInformation` (1 - 0.05) specifies that at least 95% of sequences must contain the information in the consensus, otherwise the `noConsensusChar` is used. This enables an alternative character (e.g., "+") to be substituted at positions that would otherwise yield an ambiguity code.

If `ambiguity = TRUE` (the default) then degeneracy codes in `myXStringSet` are split between their respective bases according to the `IUPAC_CODE_MAP` for DNA/RNA and `AMINO_ACID_CODE` for AA. For example, an "R" in a `DNAStrngSet` would count as half an "A" and half a "G". If `ambiguity = FALSE` then degeneracy codes are not considered in forming the consensus. For an `AAStringSet` input, the lack of degeneracy codes generally results in "X" at positions with mismatches, unless the `threshold` is set to a higher value than the default.

If `includeNonBases = TRUE` (the default) then gap ("-"), mask ("+"), and unknown (".") characters are counted towards the consensus, otherwise they are omitted from calculation of the consensus. Note that gap ("-") and unknown (".") characters are treated interchangeably as gaps when forming the consensus sequence. For this reason, the consensus of a position with all unknown (".") characters will be a gap ("-"). Also, note that if consensus is formed between different length sequences then it will represent only the longest sequences at the end. For this reason the consensus sequence is generally based on a sequence alignment such that all of the sequences have equal lengths.

Value

An XStringSet with a single consensus sequence matching the input type.

CorrectFrameshifts *Corrects Frameshift Errors In Protein Coding Sequences*

Description

Corrects the reading frame to mitigate the impact of frameshift errors caused by insertions or deletions in unaligned nucleotide sequences.

Usage

```
CorrectFrameshifts(myXStringSet,
                  myAAStringSet,
                  type = "indels",
                  acceptDistance = 0.01,
                  rejectDistance = 0.60,
                  maxComparisons = 10,
                  gapOpening = -13,
                  gapExtension = -1,
                  frameShift = -15,
                  geneticCode = GENETIC_CODE,
                  substitutionMatrix = "PFASUM50",
                  verbose = TRUE,
                  processors = 1)
```

Arguments

myXStringSet	A DNASTringSet or RNASTringSet of unaligned protein coding sequences in 5' to 3' orientation.
myAAStringSet	An AAStringSet of reference sequences having accurate translations.
type	Character string indicating the type of result desired. This should be (an abbreviation of) one of "indels", "sequences", or "both". (See details section below.)
acceptDistance	Numeric giving the maximum distance from a reference sequence that is acceptable to skip any remaining comparisons.
rejectDistance	Numeric giving the maximum distance from a reference sequence that is allowed when correcting frameshifts. Sequences in myXStringSet that are greater than rejectDistance from the nearest reference sequence will only have their length trimmed from the 3'-end to a multiple of three nucleotides without any frameshift correction.
maxComparisons	The number of reference comparisons to make before stopping the search for a closer reference sequence.
gapOpening	Numeric giving the cost for opening a gap between the query and reference sequences.
gapExtension	Numeric giving the cost for extending an open gap between the query and reference sequences.
frameShift	Numeric giving the cost for shifting between frames of the query sequence.
geneticCode	Named character vector in the same format as GENETIC_CODE (the default), which represents the standard genetic code.

substitutionMatrix	Either a substitution matrix representing the substitution scores for matching two amino acids or the name of the amino acid substitution matrix. The latter may be one of the following: "BLOSUM45", "BLOSUM50", "BLOSUM62", "BLOSUM80", "BLOSUM100", "PAM30", "PAM40", "PAM70", "PAM120", "PAM250", "PFASUM50" (the default), or "MIQS".
verbose	Logical indicating whether to display progress.
processors	The number of processors to use, or NULL to automatically detect and use all available processors.

Details

Accurate translation of protein coding sequences can be greatly disrupted by one or two nucleotide phase shifts that occasionally occur during DNA sequencing. These frameshift errors can potentially be corrected through comparison with other unshifted protein sequences. This function uses a set of reference amino acid sequences (AAStringSet) to find and correct frameshift errors in a set of nucleotide sequences (myXStringSet). First, three frame translation of the nucleotide sequences is performed, and the nearest reference sequence is selected. Then the optimal reading frame at each position is determined based on a variation of the Guan & Uberbacher (1996) method. Putative insertions and/or deletions (indels) are returned in the result, typically with close proximity to the true indel locations. For a comparison of this method to others, see Wang et al. (2013).

If type is "sequences" or "both", then frameshifts are corrected by adding N's and/or removing nucleotides. Note that this changes the nucleotide sequence, and the new sequence often has minor errors because the exact location of the indel(s) cannot be determined. However, the original frameshifts that disrupted the entire downstream sequence are reduced to local perturbations. All of the returned nucleotide sequences will have a reading frame starting from the first position. This allows direct translation, and in practice works well if there is a similar reference myAAStringSet with the correct reading frame. Hence it is more important that myAAStringSet contain a wide variety of sequences than it is that it contain a lot of sequences.

Multiple inputs control the time required for frameshift correction. The number of sequences in the reference set (myAAStringSet) will affect the speed of the first search for similar sequences. Assessing frameshifts in the second step requires order $N \times M$ time, where N and M are the lengths of the query (myXStringSet) and reference sequences. Two parameters control the number of assessments that are made for each sequence: (1) maxComparisons determines the maximum number of reference sequences to compare to each query sequence, and (2) acceptDist defines the maximum distance between a query and reference that is acceptable before continuing to the next query sequence. A lower value for maxComparisons or a higher value for acceptDist will accelerate frameshift correction, potentially at the expense of some accuracy.

Value

If type is "indels" then the returned object is a list with the same length as myXStringSet. Each element is a list with four components:

"insertions"	Approximate positions of inserted nucleotides, which could be removed to correct the reading frame, or excess nucleotides at the 3'-end that make the length longer than a multiple of three.
"deletions"	Approximate positions of deleted nucleotides, which could be added back to correct the reading frame.
"distance"	The amino acid distance from the nearest reference sequence, between 0 and 1.
"index"	The integer index of the reference sequence that was used for frame correction, or 0 if no reference sequence was within rejectDistance.

Note that positions in insertions and deletions are sometimes repeated to indicate that the same position needs to be shifted successively more than once to correct the reading frame.

If type is "sequences" then the returned object is an XStringSet of the same type as the input (myXStringSet). Nucleotides are added or deleted as necessary to correct for frameshifts. The returned sequences all have a reading frame starting from position 1, so that they can be translated directly.

If type is "both" then the returned object is a list with two components: one for the "indels" and the other for the "sequences".

CreateChimeras

Create Artificial Chimeras

Description

Creates artificial random chimeras from a set of sequences.

Usage

```

CreateChimeras(myDNAStringSet,
               numChimeras = 10,
               numParts = 2,
               minLength = 80,
               maxLength = Inf,
               minChimericRegionLength = 30,
               randomLengths = TRUE,
               includeParents = TRUE,
               processors = 1,
               verbose = TRUE)

```

Arguments

<code>myDNAStringSet</code>	A DNAStringSet object with aligned sequences.
<code>numChimeras</code>	Number of chimeras desired.
<code>numParts</code>	Number of chimeric parts from which to form a single chimeric sequence.
<code>minLength</code>	Minimum length of the complete chimeric sequence.
<code>maxLength</code>	Maximum length of the complete chimeric sequence.
<code>minChimericRegionLength</code>	Minimum length of the chimeric region of each sequence part.
<code>randomLengths</code>	Logical specifying whether to create random length chimeras in addition to random breakpoints.

`includeParents` Whether to include the parents of each chimera in the output.

`processors` The number of processors to use, or NULL to automatically detect and use all available processors.

`verbose` Logical indicating whether to display progress.

Details

Forms a set of random chimeras from the input set of (typically good quality) sequences. The chimeras are created by merging random sequences at random breakpoints. These chimeras can be used for testing the accuracy of the [FindChimeras](#) or other chimera finding functions.

Value

A `DNAStrngSet` object containing chimeras. The names of the chimeras are specified as "parent #1 name [chimeric region] (distance from parent to chimera), ...".

If `includeParents = TRUE` then the parents of the chimeras are included at the end of the result. The parents are trimmed to the same length as the chimera if `randomLengths = TRUE`. The names of the parents are specified as "parent #1 name [region] (distance to parent #2, ...)".

DB2Seqs

Export Database Sequences to a FASTA or FASTQ File

Description

Exports a database containing sequences to a FASTA or FASTQ formatted file of sequence records.

Usage

```
DB2Seqs(file,
         dbFile,
         tblName = "Seqs",
         identifier = "",
         type = "BStringSet",
         limit = -1,
         replaceChar = NA,
         nameBy = "description",
```

```

orderBy = "row_names",
removeGaps = "none",
append = FALSE,
width = 80,
compress = FALSE,
chunkSize = 1e5,
sep = ":",
clause = "",
verbose = TRUE)

```

Arguments

file	Character string giving the location where the file should be written.
dbFile	A SQLite connection object or a character string specifying the path to the database file.
tblName	Character string specifying the table in which to extract the data.
identifier	Optional character string used to narrow the search results to those matching a specific identifier. If "" then all identifiers are selected.
type	The type of XStringSet (sequences) to export to a FASTA formatted file or QualityScaledXStringSet to export to a FASTQ formatted file. This should be (an unambiguous abbreviation of) one of "DNAStringSet", "RNAStringSet", "AAStringSet", "BStringSet", "QualityScaledDNAStringSet", "QualityScaledRNAStringSet", "QualityScaledAAStringSet", or "QualityScaledBStringSet". (See details section below.)
limit	Number of results to display. The default (-1) does not limit the number of results.
replaceChar	Optional character used to replace any characters of the sequence that are not present in the XStringSet's alphabet. Not applicable if type=="BStringSet". The default (NA) results in an error if an incompatible character exist. (See details section below.)
nameBy	Character string giving the column name(s) for identifying each sequence record. If more than one column name is provided, the information in each column is concatenated, separated by sep, in the order specified.
orderBy	Character string giving the column name for sorting the results. Defaults to the order of entries in the database. Optionally can be followed by "ASC" or "DESC" to specify ascending (the default) or descending order.
removeGaps	Determines how gaps ("- " or ". " characters) are removed in the sequences. This should be (an unambiguous abbreviation of) one of "none", "all" or "common".
append	Logical indicating whether to append the output to the existing file.
width	Integer specifying the maximum number of characters per line of sequence. Not applicable when exporting to a FASTQ formatted file.
compress	Logical specifying whether to compress the output file using gzip compression.
chunkSize	Number of sequences to write to the file at a time. Cannot be less than the total number of sequences if removeGaps is "common".
sep	Character string providing the separator between fields in each sequence's name, by default pairs of colons ("::").
clause	An optional character string to append to the query as part of a "where clause".
verbose	Logical indicating whether to display status.

Details

Sequences are exported into either a FASTA or FASTQ file as determined by the type of sequences. If type is an XStringSet then sequences are exported to FASTA format. Quality information for QualityScaledXStringSets are interpreted as PredQuality scores before export to FASTQ format.

If type is "BStringSet" (the default) then sequences are exported to a FASTA file exactly the same as they were when imported. If type is "DNAStringSet" then all U's are converted to T's before export, and vice-versa if type is "RNAStringSet". All remaining characters not in the XStringSet's alphabet are converted to replaceChar or removed if replaceChar is "". Note that if replaceChar is NA (the default), it will result in an error when an unexpected character is found.

Value

Writes a FASTA or FASTQ formatted file containing the sequence records in the database.

Returns the number of sequence records written to the file.

deltaGrules

Free Energy of Hybridization of Probe/Target Quadruplets on Microarrays

Description

An 8D array with four adjacent base pairs of the probe and target sequences at a time. Each dimension has five elements defining the residue at that position ("A", "C", "G", "T", or "-"). The array contains the standard Gibbs free energy change of probe binding (dG, [kcal/mol]) for every quadruple base pairing.

Usage

```
data(deltaGrules)
```

References

SantaLucia, J., Jr., & Hicks, D. (2004) The Thermodynamics of DNA Structural Motifs. Annual Review of Biophysics and Biomolecular Structure, 33(1), 415-440. doi:10.1146/annurev.biophys.32.110601.141800.

Examples

```
data(deltaRules)
# dS of primer = AGCT / target = A-CT pairing
deltaRules["A", "G", "C", "T", "A", "-", "C", "T"]
```

 DesignArray

Design a Set of DNA Microarray Probes for Detecting Sequences

Description

Chooses the set of microarray probes maximizing sensitivity and specificity to each target consensus sequence.

Usage

```
DesignArray(myDNAStringSet,
            maxProbeLength = 24,
            minProbeLength = 20,
            maxPermutations = 4,
            numRecordedMismatch = 500,
            numProbes = 10,
            start = 1,
            end = NULL,
            maxOverlap = 5,
            hybridizationFormamide = 10,
            minMeltingFormamide = 15,
            maxMeltingFormamide = 20,
            minScore = -1e+12,
            processors = 1,
            verbose = TRUE)
```

Arguments

- `myDNAStringSet` A DNAStringSet object of aligned consensus sequences.
- `maxProbeLength` The maximum length of probes, not including the poly-T spacer. Ideally less than 27 nucleotides.
- `minProbeLength` The minimum length of probes, not including the poly-T spacer. Ideally more than 18 nucleotides.
- `maxPermutations` The maximum number of probe permutations required to represent a target site. For example, if a target site has an 'N' then 4 probes are required because probes cannot be ambiguous. Typically fewer permutations are preferable because this requires less space on the microarray and simplifies interpretation of the results.
- `numRecordedMismatch` The maximum number of recorded potential cross-hybridizations for any target site.

numProbes	The target number of probes on the microarray per input consensus sequence.
start	Integer specifying the starting position in the alignment where potential forward primer target sites begin. Preferably a position that is included in most sequences in the alignment.
end	Integer specifying the ending position in the alignment where potential reverse primer target sites end. Preferably a position that is included in most sequences in the alignment.
maxOverlap	Maximum overlap in nucleotides between target sites on the sequence.
hybridizationFormamide	The formamide concentration (% vol/vol) used in hybridization at 42 degrees Celsius. Note that this concentration is used to approximate hybridization efficiency of cross-amplifications.
minMeltingFormamide	The minimum melting point formamide concentration (% vol/vol) of the designed probes. The melting point is defined as the concentration where half of the template is bound to probe.
maxMeltingFormamide	The maximum melting point formamide concentration (% vol/vol) of the designed probes. Must be greater than the minMeltingFormamide.
minScore	The minimum score of designed probes before exclusion. A greater minScore will accelerate the code because more target sites will be excluded from consideration. However, if the minScore is too high it will prevent any target sites from being recorded.
processors	The number of processors to use, or NULL to automatically detect and use all available processors.
verbose	Logical indicating whether to display progress.

Details

The algorithm begins by determining the optimal length of probes required to meet the input constraints while maximizing sensitivity to the target consensus sequence at the specified hybridization formamide concentration. This set of potential target sites is then scored based on the possibility of cross-hybridizing to the other non-target sequences. The set of probes is returned with the minimum possibility of cross-hybridizing.

Value

A data.frame with the optimal set of probes matching the specified constraints. Each row lists the probe's target sequence (name), start position, length in nucleotides, start and end position in the sequence alignment, number of permutations, score, melt point in percent formamide at 42 degrees Celsius, hybridization efficiency (hyb_eff), target site, and probe(s). Probes are designed such that the stringency is determined by the equilibrium hybridization conditions and not subsequent washing steps.

DesignPrimers

Design PCR Primers Targeting a Specific Group of Sequences

Description

Assists in the design of primer sets targeting a specific group of sequences while minimizing the potential to cross-amplify other groups of sequences.

Usage

```
DesignPrimers(tiles,
               identifier = "",
               start = 1,
               end = NULL,
               minLength = 17,
               maxLength = 26,
               maxPermutations = 4,
               minCoverage = 0.9,
               minGroupCoverage = 0.2,
               annealingTemp = 64,
               P = 4e-07,
               monovalent = 0.07,
               divalent = 0.003,
               dNTPs = 8e-04,
               minEfficiency = 0.8,
               worstScore = -Inf,
               numPrimerSets = 0,
               minProductSize = 75,
               maxProductSize = 1200,
               maxSearchSize = 1500,
               batchSize = 1000,
               maxDistance = 0.4,
               primerDimer = 1e-07,
```

```

ragged5Prime = TRUE,
taqEfficiency = TRUE,
induceMismatch = FALSE,
processors = 1,
verbose = TRUE)

```

Arguments

tiles	A set of tiles representing each group of sequences, as in the format created by the function <code>TileSeqs</code> .
identifier	Optional character string used to narrow the search results to those matching a specific identifier. Determines the target group(s) for which primers will be designed. If "" then all identifiers are selected.
start	Integer specifying the starting position in the alignment where potential forward primer target sites begin. Preferably a position that is included in most sequences in the alignment.
end	Integer specifying the ending position in the alignment where potential reverse primer target sites end. Preferably a position that is included in most sequences in the alignment.
minLength	Integer providing the minimum length of primers to consider in the design.
maxLength	Integer providing the maximum length of primers to consider in the design, which must be less than or equal to the <code>maxLength</code> of tiles.
maxPermutations	Integer providing the maximum number of permutations considered as part of a forward or reverse primer set.
minCoverage	Numeric giving the minimum fraction of the target group's sequences that must be covered with the primer set.
minGroupCoverage	Numeric giving the minimum fraction of the target group that must have sequence information (not terminal gaps) in the region covered by the primer set.
annealingTemp	Numeric indicating the desired annealing temperature that will be used in the PCR experiment.
P	Numeric giving the molar concentration of primers in the reaction.
monovalent	The molar concentration of monovalent ([Na] and [K]) ions in solution that will be used to determine a sodium equivalent concentration.
divalent	The molar concentration of divalent ([Mg]) ions in solution that will be used to determine a sodium equivalent concentration.
dNTPs	Numeric giving the molar concentration of free nucleotides added to the solution that will be used to determine a sodium equivalent concentration.
minEfficiency	Numeric giving the minimum efficiency of hybridization desired for the primer set. Note that an efficiency of 99% (0.99) will greatly lower predicted specificity of the primer set, however an efficiency of 50% (0.5) may be too low in actuality to amplify the target group due to error in melt temperature predictions.
worstScore	Numeric specifying the score cutoff to remove target sites from consideration. For example, a <code>worstScore</code> of -5 will remove all primer sets scoring below -5, although this may eventually result in no primer sets meeting the design criteria.

numPrimerSets	Integer giving the optimal number of primer sets (forward and reverse primer sets) to design. If set to zero then all possible forward and reverse primers are returned, but the primer sets minimizing potential cross-amplifications are not chosen.
minProductSize	Integer giving the minimum number of nucleotides desired in the PCR product.
maxProductSize	Integer giving the maximum number of nucleotides desired in the PCR product.
maxSearchSize	Integer giving the maximum number of nucleotides to search for false priming upstream and downstream of the expected binding site.
batchSize	Integer specifying the number of primers to simulate hybridization per batch that is passed to CalculateEfficiencyPCR.
maxDistance	Numeric specifying the maximal fraction of mismatched base pairings on a rolling basis beginning from the 3' end of the primer.
primerDimer	Numeric giving the maximum amplification efficiency of potential primer-dimer products.
ragged5Prime	Logical specifying whether the 5' end or 3' end of primer permutations targeting the same site should be varying lengths.
taqEfficiency	Logical determining whether to make use of elongation efficiency and maxDistance to increase predictive accuracy for <i>Taq</i> DNA Polymerase amplifying primers with mismatches near the 3' terminus. Note that this should be set to FALSE if using a high-fidelity polymerase with 3' to 5' exonuclease activity.
induceMismatch	Logical or integer specifying whether to induce a mismatch in the primer with the template DNA. If TRUE then a mismatch is induced at the 6th primer position. If an integer value is provided between 2 and 6 then a mismatch is induced in that primer position, where the 3'-end is defined as position 1.
processors	The number of processors to use, or NULL to automatically detect and use all available processors.
verbose	Logical indicating whether to display progress.

Details

Primers are designed for use with *Taq* DNA Polymerase to maximize sensitivity and specificity for the target group of sequences. The design makes use of *Taq*'s bias against certain 3' terminal mismatch types in order to increase specificity further than can be achieved with hybridization efficiency alone.

Primers are designed from a set of tiles to target each identifier while minimizing affinity for all other tiled groups. Arguments provide constraints that ensure the designed primer sets meet the specified criteria as well as being optimized for the particular experimental conditions. A search is conducted through all tiles in the same alignment position to estimate the chance of cross-amplification with a non-target group.

If numPrimers is greater than or equal to one then the set of forward and reverse primers that minimizes potential false positive overlap is returned. This will also initiate a thorough search through all target sites upstream and downstream of the expected binding sites to ensure that the primers do not bind to nearby positions. Lowering the maxSearchSize will speed up the thorough search at the expense of potentially missing an unexpected target site. The number of possible primer sets assessed is increased with the size of numPrimers.

Value

A different data.frame will be returned depending on number of primer sets requested. If no primer sets are required then columns contain the forward and reverse primers for every possible position scored by their potential to amplify other identified groups. If one or more primer sets are requested then columns contain information for the optimal set of forward and reverse primers that could be used in combination to give the fewest potential cross-amplifications.

Note

The program OligoArrayAux (<http://mfold.rna.albany.edu/?q=DINAMelt/OligoArrayAux>) must be installed in a location accessible by the system. For example, the following code should print the installed OligoArrayAux version when executed from the R console:

```
system("hybrid-min -V")
```

To install OligoArrayAux from the downloaded source folder on Unix-like platforms, open the shell (or Terminal on Mac OS) and type:

```
cd oligoarrayaux # change directory to the correct folder name
./configure
make
sudo make install
```

DesignProbes

*Design FISH Probes Targeting a Specific Group of Sequences***Description**

Assists in the design of single or dual probes targeting a specific group of sequences while minimizing the potential to cross-hybridize with other groups of sequences.

Usage

```
DesignProbes(tiles,
             identifier = "",
             start = 1,
             end = NULL,
             minLength = 17,
             maxLength = 26,
             maxPermutations = 4,
             minCoverage = 0.9,
             minGroupCoverage = 0.2,
             hybTemp = 46,
             P = 2.5e-07,
             Na = 1,
             FA = 35,
             minEfficiency = 0.5,
             worstScore = -Inf,
             numProbeSets = 0,
             batchSize = 1000,
             target = "SSU",
             verbose = TRUE)
```

Arguments

tiles	A set of tiles representing each group of sequences, as in the format created by the function <code>TileSeqs</code> .
identifier	Optional character string used to narrow the search results to those matching a specific identifier. Determines the target group(s) for which probes will be designed. If "" then all identifiers are selected.
start	Integer specifying the starting position in the alignment where potential target sites begin. Preferably a position that is included in most sequences in the alignment.
end	Integer specifying the ending position in the alignment where potential target sites end. Preferably a position that is included in most sequences in the alignment.
minLength	Integer providing the minimum length of probes to consider in the design.
maxLength	Integer providing the maximum length of probes to consider in the design, which must be less than or equal to the <code>maxLength</code> of tiles.
maxPermutations	Integer providing the maximum number of probe permutations required to reach the desired coverage of a target site.

minCoverage	Numeric giving the minimum fraction of the target group's sequences that must be covered by the designed probe(s).
minGroupCoverage	Numeric giving the minimum fraction of the target group that must have sequence information (not terminal gaps) in the target site's region.
hybTemp	Numeric specifying the hybridization temperature, typically 46 degrees Celsius.
P	Numeric giving the molar concentration of probes during hybridization.
Na	Numeric giving the molar sodium concentration in the hybridization buffer. Values may range between 0.01M and 1M. Note that salt correction from 1 molar is not available for the thermodynamic rules of RNA/RNA interactions.
FA	Numeric concentration (as percent v/v) of the denaturant formamide in the hybridization buffer.
minEfficiency	Numeric giving the minimum equilibrium hybridization efficiency desired for designed probe(s) at the defined experimental conditions.
worstScore	Numeric specifying the score cutoff to remove target sites from consideration. For example, a worstScore of -5 will remove all probes scoring below -5, although this may eventually result in no probes meeting the design criteria.
numProbeSets	Integer giving the optimal number of dual probe sets to design. If set to zero then all potential single probes are returned, and the probe sets minimizing potential false cross-hybridizations are not chosen.
batchSize	Integer specifying the number of probes to simulate hybridization per batch that is passed to CalculateEfficiencyFISH.
target	The target molecule used in the generation of tiles. Either "SSU" for the small-subunit rRNA, "LSU" for the large-subunit rRNA, or "Other". Used to determine the domain for dG3 calculations, which is plus or minus 200 nucleotides of the target site if "Other".
verbose	Logical indicating whether to display progress.

Details

Probes are designed to maximize sensitivity and specificity to the target group(s) (*identifier(s)*). If *numProbeSets* > 0 then that many pairs of probes with minimal cross-hybridization overlap are returned, enabling increased specificity with a dual-color approach.

Probes are designed from a set of tiles to target each *identifier* while minimizing affinity for all other tiled groups. Arguments provide constraints that ensure the designed probes meet the specified criteria as well as being optimized for the particular experimental conditions. A search is conducted through all tiles in the same alignment position to estimate the chance of cross-hybridization with a non-target group.

Two models are used in design, both of which were experimentally calibrated using denaturation profiles from 5 organisms belonging to all three domains of life. Probe lengths are chosen to meet the *minEfficiency* using a fast model of probe-target hybridization. Candidate probes are then confirmed using a slower model that also takes into account probe-folding and target-folding. Finally, probes are scored for their inability to cross-hybridize with non-target groups by using the fast model and taking into account any mismatches.

Value

A different *data.frame* will be returned depending on number of primer sets requested. If no probe sets are required then columns contain the designed probes for every possible position scored

by their potential to cross-hybridize with other identified groups. If one or more probe sets are requested then columns contain information for the optimal set of probes (probe one and probe two) that could be used in combination to give the fewest potential cross-hybridizations.

Note

The program OligoArrayAux (<http://mfold.rna.albany.edu/?q=DINAMelt/OligoArrayAux>) must be installed in a location accessible by the system. For example, the following code should print the installed OligoArrayAux version when executed from the R console:

```
system("hybrid-min -V")
```

To install OligoArrayAux from the downloaded source folder on Unix-like platforms, open the shell (or Terminal on Mac OS) and type:

```
cd oligoarrayaux # change directory to the correct folder name
./configure
make
sudo make install
```

## Not run: probes <- DesignProbes(tiles, identifier="Enterobacteriales", start=280, end=420)
```

Description

Aids the design of pairs of primers for amplifying a unique "signature" from each group of sequences. Signatures are distinct PCR products that can be differentiated by their length, melt temperature, or sequence.

Usage

```
DesignSignatures(dbFile,
                 tblName = "Seqs",
                 identifier = "",
                 focusID = NA,
                 type = "melt",
                 resolution = 0.5,
                 levels = 10,
                 enzymes = NULL,

                 ampEfficiency = 0.5,
                 numPrimerSets = 100,
                 minProductSize = 70,
                 maxProductSize = 400,
                 kmerSize = 8,
                 searchPrimers = 500,
                 maxDictionary = 20000,
                 primerDimer = 1e-07,
                 pNorm = 1,
                 taqEfficiency = TRUE,
                 processors = 1,
                 verbose = TRUE)
```

Arguments

dbFile	A SQLite connection object or a character string specifying the path to the database file.
tblName	Character string specifying the table where the DNA sequences are located.
identifier	Optional character string used to narrow the search results to those matching a specific identifier. Determines the target group(s) for which primers will be designed. If "" then all identifiers are selected.
focusID	Optional character string specifying which of the identifiers will be used in the initial step of designing primers. If NA (the default), then the identifier with the most sequence information is used as the focusID.
type	Character string indicating the type of signature being used to differentiate the PCR products from each group. This should be (an abbreviation of) one of "melt", "length", or "sequence".
resolution	Numeric specifying the "resolution" of the experiment, or a vector giving the boundaries of bins. (See details section below.)
levels	Numeric giving the number of "levels" that can be distinguished in each bin. (See details section below.)
enzymes	Named character vector providing the cut sites of one or more restriction enzymes. Cut sites must be delineated in the same format as RESTRICTION_ENZYMES .

minLength	Integer providing the minimum length of primers to consider in the design.
maxLength	Integer providing the maximum length of primers to consider in the design.
maxPermutations	Integer providing the maximum number of permutations allowed in a forward or reverse primer to attain greater coverage of sequences.
annealingTemp	Numeric indicating the desired annealing temperature that will be used in the PCR experiment.
P	Numeric giving the molar concentration of primers in the reaction.
monovalent	The molar concentration of monovalent ([Na] and [K]) ions in solution that will be used to determine a sodium equivalent concentration.
divalent	The molar concentration of divalent ([Mg]) ions in solution that will be used to determine a sodium equivalent concentration.
dNTPs	Numeric giving the molar concentration of free nucleotides added to the solution that will be used to determine a sodium equivalent concentration.
minEfficiency	Numeric giving the minimum efficiency of hybridization desired for the primer set.
ampEfficiency	Numeric giving the minimum efficiency required for theoretical amplification of the primers. Note that ampEfficiency must be less than or equal to minEfficiency. Lower values of ampEfficiency will allow for more PCR products, although very low values are unrealistic experimentally.
numPrimerSets	Integer giving the optimal number of primer sets (forward and reverse primer sets) to design.
minProductSize	Integer giving the minimum number of nucleotides desired in the PCR product.
maxProductSize	Integer giving the maximum number of nucleotides desired in the PCR product.
kmerSize	Integer giving the size of k-mers to use in the preliminary search for potential primers.
searchPrimers	Numeric specifying the number of forward and reverse primers to use in searching for potential PCR products. A lower value will result in a faster search, but potentially neglect some useful primers.
maxDictionary	Numeric giving the maximum number of primers to search for simultaneously in any given step.
primerDimer	Numeric giving the maximum amplification efficiency of potential primer-dimer products.
pNorm	Numeric specifying the power ($p > 0$) used in calculating the L^p -norm when scoring primer pairs. By default ($p = 1$), the score is equivalent to the average difference between pairwise signatures. When $p < 1$, many small differences will be preferred over fewer large differences, and vice-versa when $p > 1$. This enables prioritizing primer pairs that will yield a greater number of unique signatures ($p < 1$), or fewer distinct, but more dissimilar, signatures ($p > 1$).
taqEfficiency	Logical determining whether to make use of elongation efficiency to increase predictive accuracy for <i>Taq</i> DNA Polymerase amplifying primers with mismatches near the 3' terminus. Note that this should be set to FALSE if using a high-fidelity polymerase with 3' to 5' exonuclease activity.
processors	The number of processors to use, or NULL to automatically detect and use all available processors.
verbose	Logical indicating whether to display progress.

Details

Signatures are group-specific PCR products that can be differentiated by either their melt temperature profile, length, or sequence. DesignSignatures assists in finding the optimal pair of forward and reverse primers for obtaining a distinguishable signature from each group of sequences. Groups are delineated by their unique identifier in the database. The algorithm works by progressively narrowing the search for optimal primers: (1) the most frequent k-mers are found; (2) these are used to design primers initially matching the focusID group; (3) the most common forward and reverse primers are selected based on all of the groups, and ambiguity is added up to maxPermutations; (4) a final search is performed to find the optimal forward and reverse primer. Pairs of primers are scored by the distance between the signatures generated for each group, which depends on the type of experiment.

The arguments resolution and levels control the theoretical resolving power of the experiment. The signature for a group is discretized or grouped into "bins" each with a certain magnitude of the signal. Here resolution determines the separation between distinguishable "bins", and levels controls the range of values in each bin. A high-accuracy experiment would have many bins and/or many levels. While levels is interpreted similarly for every type of experiment, resolution is treated differently depending on type. If type is "melt", then resolution can be either a vector of different melt temperatures, or a single number giving the change in temperatures that can be differentiated. A high-resolution melt (HRM) assay would typically have a resolution between 0.25 and 1 degree Celsius. If type is "length" then resolution is either the number of bins between the minProductSize and maxProductSize, or the bin boundaries. For example, resolution can be lower (wider bins) at long lengths, and higher (narrower bins) at shorter lengths. If type is "sequence" then resolution sets the k-mer size used in differentiating amplicons. Oftentimes, 4 to 6-mers are used for the classification of amplicons.

The signatures can be diversified by using a restriction enzyme to digest the PCR products when type is "melt" or "length". If enzymes are supplied then an additional search is made to find the best enzyme to use with each pair of primers. In this case, the output includes all of the primer pairs, as well as any enzymes that will digest the PCR products of that primer pair. The output is re-scored to rank the top primer pair and enzyme combination. Note that enzymes is inapplicable when type is "sequence" because restriction enzymes do not alter the sequence of the DNA. Also, it is recommended that only a subset of the available RESTRICTION_ENZYMES are used as input enzymes in order to accelerate the search for the best enzyme.

Value

A data.frame with the top-scoring pairs of forward and reverse primers, their score, the total number of PCR products, and associated columns for the restriction enzyme (if enzyme is not NULL).

 DigestDNA

 Simulate Restriction Digestion of DNA

Description

Restriction enzymes can be used to cut double-stranded DNA into fragments at specific cut sites. DigestDNA performs an *in-silico* restriction digest of the input DNA sequence(s) given one or more restriction sites.

Usage

```
DigestDNA(sites,  
          myDNAStringSet,  
          type = "fragments",  
          strand = "both")
```

Arguments

sites	A character vector of DNA recognition sequences and their enzymes' corresponding cut site(s).
myDNAStringSet	A DNAStringSet object or character vector with one or more sequences in 5' to 3' orientation.
type	Character string indicating the type of results desired. This should be (an abbreviation of) either "fragments" or "positions".
strand	Character string indicating the strand(s) to cut. This should be (an abbreviation of) one of "both", "top", or "bottom". The top strand is defined as the input DNAStringSet sequence, and the bottom strand is its reverse complement.

Details

In the context of a restriction digest experiment with a known DNA sequence, it can be useful to predict the expected DNA fragments *in-silico*. Restriction enzymes make cuts in double-stranded DNA at specific positions near their recognition site. The recognition site may be somewhat ambiguous, as represented by the IUPAC_CODE_MAP. Cuts that occur at different positions on the top and bottom strands result in sticky-ends, whereas those that occur at the same position result in fragments with blunt-ends. Multiple restriction sites can be supplied to simultaneously digest the DNA. In this case, sites for the different restriction enzymes may be overlapping, which could result in multiple close-proximity cuts that would not occur experimentally. Also, note that cut sites will not be matched to non-DNA_BASES in myDNAStringSet.

Value

DigestDNA can return two types of results: cut positions or the resulting DNA fragments corresponding to the top, bottom, or both strands. If type is "positions" then the output is a list with the cut location(s) in each sequence in myDNAStringSet. The cut location is defined as the position after the cut relative to the 5'-end. For example, a cut at 6 would occur between positions 5 and 6, where the respective strand's 5' nucleotide is defined as position 1.

If type is "fragments" (the default), then the result is a DNAStringSetList. Each element of the list contains the top and/or bottom strand fragments after digestion of myDNAStringSet, or the original sequence if no cuts were made. Sequences are named by whether they originated from the top or bottom strand, and list elements are named based on the input DNA sequences. The top strand is defined by myDNAStringSet as it is input, whereas the bottom strand is its reverse complement.

Disambiguate

Expand Ambiguities into All Permutations of a DNASTringSet

Description

Performs the inverse function of `ConsensusSequence` by expanding any ambiguities present in sequences.

Usage

```
Disambiguate(myXStringSet)
```

Arguments

`myXStringSet` A `DNASTringSet` or `RNASTringSet` object of sequences.

Details

Ambiguity codes in the `IUPAC_CODE_MAP` can be used to represent multiple nucleotides at a single position. Using these letters, multiple oligonucleotide permutations can be represented with a single ambiguous sequence. This function expands each sequence in the `DNASTringSet` input into all of its permutations. Note that sequences with many ambiguities can result in a very large number of potential permutations.

Value

A `DNASTringSetList` or `RNASTringSetList` with one element for each sequence in `myXStringSet`.

Author(s)

Erik Wright <eswright@pitt.edu>

See Also[ConsensusSequence](#)**Examples**

```
dna <- DNASTringSet(c("ACST", "NNN"))
dna_list <- Disambiguate(dna)
dna_list[[1]]
dna_list[[2]]
unlist(dna_list)

rna <- RNASTringSet(c("ACGU", "AGAU")) # 2 permutations
rna <- ConsensusSequence(rna) # "ASRU"
Disambiguate(rna) # 4 permutations
```

DistanceMatrix

*Calculate the Distances Between Sequences***Description**

Calculates a distance matrix for an XStringSet. Each element of the distance matrix corresponds to the dissimilarity between two sequences in the XStringSet.

Usage

```
DistanceMatrix(myXStringSet,
               type = "matrix",
               includeTerminalGaps = FALSE,
               penalizeGapLetterMatches = TRUE,
               penalizeGapGapMatches = FALSE,
               correction = "none",
               processors = 1,
               verbose = TRUE)
```

Arguments

myXStringSet An XStringSet object of aligned sequences (DNASTringSet, RNASTringSet, or AAStringSet).

type Character string indicating the type of output desired. This should be either "matrix" or "dist". (See value section below.)

includeTerminalGaps Logical specifying whether or not to include terminal gaps ("- or ." characters on each end of the sequence) into the calculation of distance.

penalizeGapLetterMatches Logical specifying whether or not to consider gap-to-letter matches as mismatches. If FALSE, then gap-to-letter matches are not included in the total length used to calculate distance.

penalizeGapGapMatches Logical specifying whether or not to consider gap-to-gap matches as mismatches. If FALSE (the default), then gap-to-gap matches are not included in the total length used to calculate distance.

correction	The substitution model used for distance correction. This should be (an abbreviation of) either "none" or "Jukes-Cantor".
processors	The number of processors to use, or NULL to automatically detect and use all available processors.
verbose	Logical indicating whether to display progress.

Details

The uncorrected distance matrix represents the hamming distance between each of the sequences in `myXStringSet`. Ambiguity can be represented using the characters of the `IUPAC_CODE_MAP` for `DNAStrngSet` and `RNAStringSet` inputs, or using the `AMINO_ACID_CODE` for an `AAStringSet` input. For example, the distance between an 'N' and any other nucleotide base is zero. The letters B (N or D), J (I or L), Z (Q or E), and X (any letter) are degenerate in the `AMINO_ACID_CODE`.

If `includeTerminalGaps = FALSE` then terminal gaps ("- " or ". " characters) are not included in sequence length. This can be faster since only the positions common to each pair of sequences are compared. Sequences with no overlapping region in the alignment are given a value of NA, unless `includeTerminalGaps = TRUE`, in which case distance is 100%.

Penalizing gap-to-gap and gap-to-letter mismatches specifies whether to penalize these special mismatch types and include them in the total length when calculating distance. Both "- " and ". " characters are interpreted as gaps. The default behavior is to calculate distance as the fraction of positions that differ across the region of the alignment shared by both sequences (not including gap-to-gap matches).

The elements of the distance matrix can be referenced by `dimnames` corresponding to the names of the `XStringSet`. Additionally, an attribute named "correction" specifying the method of correction used can be accessed using the function `attr`.

Value

If `type` is "matrix", a symmetric matrix where each element is the distance between the sequences referenced by the respective row and column. The `dimnames` of the matrix correspond to the names of the `XStringSet`.

If `type` is "dist", an object of class "dist" that contains one triangle of the distance matrix as a vector. Since the distance matrix is symmetric, storing only one triangle is more memory efficient.

dna
d <- DistanceMatrix(dna, includeTerminalGaps=TRUE,
                    penalizeGapGapMatches=FALSE)
# d[1,2] is still 2 bases in 5 = 0.40

```

FindChimeras

Find Chimeras in a Sequence Database

Description

Finds chimeras present in a database of sequences. Makes use of a reference database of (presumed to be) good quality sequences.

Usage

```

FindChimeras(dbFile,
             tblName = "Seqs",
             identifier = "",
             dbFileReference,
             tblNameReference = "Seqs",
             batchSize = 100,
             minNumFragments = 20000,
             tb.width = 5,

```

```

multiplier = 20,
minLength = 30,
minCoverage = 0.6,
overlap = 100,
minSuspectFragments = 4,
showPercentCoverage = FALSE,
add2tbl = FALSE,
maxGroupSize = -1,
minGroupSize = 25,
excludeIDs = NULL,
processors = 1,
verbose = TRUE)

```

Arguments

dbFile	A SQLite connection object or a character string specifying the path to the database file to be checked for chimeric sequences.
tblName	Character string specifying the table in which to check for chimeras.
identifier	Optional character string used to narrow the search results to those matching a specific identifier. If "" then all identifiers are selected.
dbFileReference	A SQLite connection object or a character string specifying the path to the reference database file of (presumed to be) good quality sequences. A 16S reference database is available from http://DECIPHER.codes .
tblNameReference	Character string specifying the table with reference sequences.
batchSize	Number sequences to tile with fragments at a time.
minNumFragments	Number of suspect fragments to accumulate before searching through other groups.
tb.width	A single integer [1..14] giving the number of nucleotides at the start of each fragment that are part of the trusted band.
multiplier	A single integer specifying the multiple of fragments found out-of-group greater than fragments found in-group in order to consider a sequence a chimera.
minLength	Minimum length of a chimeric region in order to be considered as a chimera.
minCoverage	Minimum fraction of coverage necessary in a chimeric region.
overlap	Number of nucleotides at the end of the sequence that the chimeric region must overlap in order to be considered a chimera.
minSuspectFragments	Minimum number of suspect fragments belonging to another group required to consider a sequence a chimera.
showPercentCoverage	Logical indicating whether to list the percent coverage of suspect fragments in each chimeric region in the output.
add2tbl	Logical or a character string specifying the table name in which to add the result.
maxGroupSize	Maximum number of sequences searched in a group. A value of less than 0 means the search is unlimited.

minGroupSize	The minimum number of sequences in a group to be considered as part of the search for chimeras. May need to be set to a small value for reference databases with mostly small groups.
excludeIDs	Optional character vector of identifier(s) to exclude from database searches, or NULL (the default) to not exclude any.
processors	The number of processors to use, or NULL to automatically detect and use all available processors.
verbose	Logical indicating whether to display progress.

Details

FindChimeras works by finding suspect fragments that are uncommon in the group where the sequence belongs, but very common in another group where the sequence does not belong. Each sequence in the dbFile is tiled into short sequence segments called fragments. If the fragments are infrequent in their respective group in the dbFileReference then they are considered suspect. If enough suspect fragments from a sequence meet the specified constraints then the sequence is flagged as a chimera.

The default parameters are optimized for full-length 16S sequences (> 1,000 nucleotides). Shorter 16S sequences require two parameters that are different than the defaults: minCoverage = 0.2, and minSuspectFragments = 2.

Groups are determined by the identifier present in each database. For this reason, the groups in the dbFile should exist in the groups of the dbFileReference. The reference database is assumed to contain many sequences of only good quality.

If a reference database is not present then it is feasible to create a reference database by using the input database as the reference database. Removing chimeras from the reference database and then iteratively repeating the process can result in a clean reference database.

For non-16S sequences it may be necessary to optimize the parameters for the particular sequences. The simplest way to perform an optimization is to experiment with different input parameters on artificial chimeras such as those created using [CreateChimeras](#). Adjusting input parameters until the maximum number of artificial chimeras are identified is the easiest way to determine new defaults.

Value

A data.frame containing only the sequences that meet the specifications for being chimeric. The chimera column contains information on the chimeric region and to which group it belongs. The row.names of the data.frame correspond to those of the sequences in the dbFile.

FindSynteny

*Finds Synteny in a Sequence Database***Description**

Finds syntenic blocks between groups of sequences in a database.

Usage

```
FindSynteny(dbFile,
            tblName = "Seqs",
            identifier = "",
            useFrames = TRUE,
            alphabet = AA_REDUCED[[1]],
            geneticCode = GENETIC_CODE,
            sepCost = 0,
            gapCost = -0.01,
            shiftCost = 0,
            codingCost = 0,
            maxSep = 2000,
            maxGap = 5000,
            minScore = 30,
            dropScore = -100,
            maskRepeats = TRUE,
            allowOverlap = FALSE,
            storage = 0.5,
            processors = 1,
            verbose = TRUE)
```

Arguments

dbFile	A SQLite connection object or a character string specifying the path to the database file.
tblName	Character string specifying the table where the sequences are located.
identifier	Optional character string used to narrow the search results to those matching a specific identifier. If "" then all identifiers are selected.
useFrames	Logical specifying whether to use 6-frame amino acid translations to help find more distant hits. Using the alphabet is helpful when the genome is largely composed of coding DNA. If FALSE then faster but less sensitive to distant homology.
alphabet	Character vector of amino acid groupings used to reduce the 20 standard amino acids into smaller groups. Alphabet reduction helps to find more distant homologies between sequences. A non-reduced amino acid alphabet can be used by setting alphabet equal to AA_STANDARD.

geneticCode	Either a character vector giving the genetic code to use in translation, or a list containing one genetic code for each identifier. If a list is provided then it must be named by the corresponding identifiers in the database.
sepCost	Cost per nucleotide separation between hits to apply when chaining hits into blocks.
gapCost	Cost for gaps between hits to apply when chaining hits into blocks.
shiftCost	Cost for shifting between different reading frames when chaining reduced amino acid hits into blocks.
codingCost	Cost for switching between coding and non-coding hits when chaining hits into blocks.
maxSep	Maximal separation (in nucleotides) between hits in the same block.
maxGap	The maximum number of gaps between hits in the same block.
minScore	The minimum score required for a chain of hits to become a block. Higher values of minScore are less likely to yield false positives.
dropScore	The change from maximal score required to stop extending blocks.
maskRepeats	Logical specifying whether to “soft” mask repeats when searching for hits.
allowOverlap	Logical specifying whether to permit blocks to overlap on the same sequence.
storage	Excess gigabytes available to store objects so that they do not need to be re-computed in later steps. This should be a number between zero and a (modest) fraction of the available system memory. Note that more than storage gigabytes may be required, but will not be stored for later reuse.
processors	The number of processors to use, or NULL to automatically detect and use all available processors.
verbose	Logical indicating whether to display progress.

Details

Long nucleotide sequences, such as genomes, are often not collinear or may be composed of many smaller segments (e.g., contigs). FindSynteny searches for “hits” between sequences that can be chained into collinear “blocks” of synteny. Hits are defined as k-mer exact nucleotide matches or k-mer matches in a reduced amino acid alphabet (if useFrames is TRUE). Hits are chained into blocks as long as they are: (1) within the same sequence, (2) within maxSep and maxGap distance, and (3) help maintain the score above minScore. Blocks are extended from their first and last hit until their score drops below dropScore from the maximum that was reached. This process results in a set of hits and blocks stored in an object of class “Synteny”.

Value

An object of class “Synteny”.

Note

FindSynteny is intended to be used on sets of sequences with up to ~100 million nucleotides total per identifier. For this reason, better performance can sometimes be achieved by assigning a unique identifier to each chromosome belonging to a large genome.

```

 FormGroups

Forms Groups By Rank

Description

Agglomerates sequences into groups within a specified size range based on taxonomic rank.

Usage

```
FormGroups(dbFile,
            tblName = "Seqs",
            goalSize = 50,
            minGroupSize = 25,
            maxGroupSize = 5000,
            includeNames = FALSE,
            add2tbl = FALSE,
            verbose = TRUE)
```

Arguments

dbFile	A SQLite connection object or a character string specifying the path to the database file.
tblName	Character string specifying the table where the rank information is located.
goalSize	Number of sequences required in each group to stop adding more sequences.
minGroupSize	Minimum number of sequences in each group required to stop trying to recombine with a larger group.
maxGroupSize	Maximum number of sequences in each group allowed to continue agglomeration.
includeNames	Logical indicating whether to include the formal scientific name in the group name.
add2tbl	Logical or a character string specifying the table name in which to add the result.
verbose	Logical indicating whether to display progress.

Details

FormGroups uses the “rank” field in the dbFile table to group sequences with similar taxonomic rank. Rank information must be present in the tblName, such as that created by default when importing sequences from a GenBank formatted file.

Rank information contains the formal scientific name on the first line, followed by the taxonomic lineage on subsequent lines. When includeNames is TRUE the formal scientific name is appended to the end of the group name, otherwise only the taxonomic lineage is used as the group name.

The algorithm ascends the taxonomic tree, agglomerating taxa into groups until the goalSize is reached. If the group size is below minGroupSize then further agglomeration is attempted with a larger group. If additional agglomeration results in a group larger than maxGroupSize then the agglomeration is undone so that the group is smaller. Setting minGroupSize to goalSize avoids the creation of polyphyletic groups. Note that this approach may often result in paraphyletic groups.

Value

A data.frame with the rank and corresponding group name as identifier. Note that quotes are stripped from group names to prevent problems that they may cause. The origin gives the rank preceding the identifier. The count denotes number of sequences corresponding to each rank. If add2tbl is not FALSE then the “identifier” and “origin” columns are updated in dbFile.

```

HEC_MI

Mutual Information for Protein Secondary Structure Prediction

Description

Arrays containing values of mutual information for single residues (HEC_MI1) and pairs of residues (HEC_MI2) located within 10 residues of the position being predicted (position "0"). The arrays have dimensions corresponding to the 20 (standard) amino acids, positions (-10 to 10), and states (helix ("H"), sheet ("E"), or coil ("C")).

Usage

```
data("HEC_MI1")
data("HEC_MI2")
```

Format

The format of HEC_MI1 is: num [1:20, 1:21, 1:3] 0.04264 -0.00117 0.02641 0.08264 -0.04876 ...
 - attr(*, "dimnames")=List of 3 ..\$: chr [1:20] "A" "R" "N" "D"\$: chr [1:21] "-10" "-9" "-8"
 "-7"\$: chr [1:3] "H" "E" "C"

The format of HEC_MI2 is: num [1:20, 1:20, 1:21, 1:21, 1:3] 2.56 -Inf -Inf -Inf -Inf ... - attr(*,
 "dimnames")=List of 5 ..\$: chr [1:20] "A" "R" "N" "D"\$: chr [1:20] "A" "R" "N" "D"\$:
 chr [1:21] "-10" "-9" "-8" "-7"\$: chr [1:21] "-10" "-9" "-8" "-7"\$: chr [1:3] "H" "E" "C"

Details

The values in each matrix were derived based on a set of 15,201 proteins in the ASTRAL Compendium (Chandonia, 2004). The 8-states assigned by the Dictionary of Protein Secondary Structure (DSSP) were reduced to 3-states via H = G, H, or I; E = E; and C = B, S, C, or T.

Examples

```
data(HEC_MI1)
# the contribution of an arginine ("R")
# located 3 residues left of center
# to a helical ("H") state at the center
HEC_MI1["R", "-3", "H"]

data(HEC_MI2)
# the contribution of arginine and lysine ("K")
# located at positions -1 and +1, respectively
# to a coil ("C") state at the center position
HEC_MI2["R", "K", "-1", "1", "C"]

matplot(-10:10, t(HEC_MI1[, , "H"]),
        type="l", col=1:8, lty=rep(1:3, each=8),
        xlab="Amino Acid Position Relative to Center",
        ylab="Log-Odds of Helix at Center Position")
legend("bottomleft",
       lwd=1, col=1:8, lty=rep(1:3, each=8),
       legend=dimnames(HEC_MI1)[[1]], ncol=2)
```

Description

Groups the sequences into clusters of similarity or creates a tree from a set of sequences.

Usage

```

IdClusters(myDistMatrix = NULL,
           method = "UPGMA",
           cutoff = -Inf,
           showPlot = FALSE,
           type = "clusters",
           myXStringSet = NULL,
           model = MODELS,
           collapse = 0,
           processors = 1,
           verbose = TRUE)

```

Arguments

<code>myDistMatrix</code>	A symmetric $N \times N$ distance matrix with the values of dissimilarity between N sequences, an object of class 'dist', or NULL if method is "inexact".
<code>method</code>	An agglomeration method to be used. This should be (an abbreviation of) one of "complete", "single", "UPGMA", "WPGMA", "NJ", "ML", or "inexact". (See details section below.)
<code>cutoff</code>	A vector with the maximum edge length separating the sequences in the same cluster. Multiple cutoffs may be provided in ascending or descending order. (See details section below.)
<code>showPlot</code>	Logical specifying whether or not to plot the resulting dendrogram. Not applicable if method='inexact'.
<code>type</code>	Character string indicating the type of output desired. This should be (an abbreviation of) one of "clusters", "dendrogram", or "both". Not applicable if method='inexact'. (See value section below.)
<code>myXStringSet</code>	If method is "ML", the DNAXStringSet or RNAXStringSet used in the creation of myDistMatrix. If method is "inexact", the DNAXStringSet, RNAXStringSet, or AAXStringSet to cluster. Not applicable for other methods.
<code>collapse</code>	Numeric controlling which internal edges of the tree are removed by collapsing their nodes. If collapse is zero (the default) then nodes at the same height will be collapsed to a single node, resulting in a multifurcating tree. When collapse is greater than zero, nodes that are within collapse difference in height are made into a single node. A value of collapse less than zero will ensure that the dendrogram is purely bifurcating. Note that collapse has no effect on cluster numbers or cutoff.
<code>model</code>	One or more of the available MODELS of DNA evolution. Only applicable if method is "ML".
<code>processors</code>	The number of processors to use, or NULL to automatically detect and use all available processors.
<code>verbose</code>	Logical indicating whether to display progress.

Details

IdClusters groups the input sequences into clusters using a set of dissimilarities representing the distance between N sequences. In most cases, a phylogenetic tree is formed using the specified method. Then each leaf (sequence) of the tree is assigned to a cluster based on its edge lengths to the other sequences. The available clustering methods are described as follows:

Ultrametric methods: The method `complete` assigns clusters using complete-linkage so that sequences in the same cluster are no more than `cutoff` distance apart. The method `single` assigns clusters using single-linkage so that sequences in the same cluster are within `cutoff` of at least one other sequence in the same cluster. UPGMA (the default) or WPGMA assign clusters using average-linkage which is a compromise between the sensitivity of complete-linkage clustering to outliers and the tendency of single-linkage clustering to connect distant relatives that do not appear to be closely related. UPGMA produces an unweighted tree, where each leaf contributes equally to the average edge lengths, whereas WPGMA produces a weighted result.

Additive methods: NJ uses the Neighbor-Joining method proposed by Saitou and Nei that does not assume lineages evolve at the same rate (the molecular clock hypothesis). The NJ method is typically the most phylogenetically accurate of the above distance-based methods. ML creates a neighbor-joining tree and then iteratively maximizes the likelihood of the tree given the aligned sequences (`myXStringSet`). This is accomplished through a combination of optimizing edge lengths with Brent's method and improving tree topology with nearest-neighbor interchanges (NNIs). When `method="ML"`, one or more MODELS of DNA evolution must be specified. Model parameters are iteratively optimized to maximize likelihood, except base frequencies which are empirically determined. If multiple models are given, the best model is automatically chosen based on BIC calculated from the likelihood and the sample size (defined as the number of variable sites in the DNA sequence).

Sequence-only method: `inexact` uses a heuristic algorithm to directly assign sequences to clusters without a distance matrix. First the sequences are ordered by length and the longest sequence becomes the first cluster seed. If the second sequence is less than `cutoff` percent distance then it is added to the cluster, otherwise it becomes a new cluster representative. The remaining sequences are matched to cluster representatives based on their k-mer distribution and then aligned to find the closest sequence. This approach is repeated until all sequences belong to a cluster. In the vast majority of cases, this process results in clusters with members separated by less than `cutoff` distance, where distance is defined as the percent dissimilarity between the overlapping region of a "glocal" alignment.

For all methods, multiple cutoffs may be provided in sorted order. If the cutoffs are provided in *descending* order then clustering at each new value of `cutoff` is continued within the prior `cutoff`'s clusters. In this way clusters at lower values of `cutoff` are completely contained within their umbrella clusters at higher values of `cutoff`. This is useful for defining taxonomy, where groups need to be hierarchically nested. If multiple cutoffs are provided in *ascending* order then clustering at each level of `cutoff` is independent of the prior level. This may result in fewer high-level clusters for NJ and ML methods, but will have no impact on ultrametric methods.

Value

If `type` is `"clusters"` (the default), then a `data.frame` is returned with a column for each `cutoff` specified. This `data.frame` has dimensions $N * M$, where each one of N sequences is assigned to a cluster at the M -level of `cutoff`. The `row.names` of the `data.frame` correspond to the `dimnames` of `myDistMatrix`. If `type` is `"dendrogram"`, then an object of class `dendrogram` is returned that can be used for plotting. Leaves of the dendrogram are colored by cluster number, but the same color may be repeated for different clusters. Note that the cophenetic distance between leaves of the tree is equal to the sum of branch lengths separating the leaves. This is different than trees produced by `hclust` where leaves are merged at a height equal to their cophenetic distance. If `type` is `"both"` then a list is returned containing both the `"clusters"` and `"dendrogram"` outputs.

IdConsensus

Create Consensus Sequences by Groups

Description

Forms a consensus sequence representing the sequences in each group.

Usage

```
IdConsensus(dbFile,
            tblName = "Seqs",
            identifier = "",
            type = "DNAStringSet",
            colName = "identifier",
            processors = 1,
            verbose = TRUE,
            ...)
```

Arguments

dbFile	A SQLite connection object or a character string specifying the path to the database file.
tblName	Character string specifying the table in which to form consensus.
identifier	Optional character string used to narrow the search results to those matching a specific identifier. If "" then all identifiers are selected.
type	The type of XStringSet (sequences) to use in forming consensus. This should be (an abbreviation of) one of "DNAStringSet", "RNAStringSet", "AAStringSet", or "BStringSet".
colName	Column containing the group name of each sequence.
processors	The number of processors to use, or NULL to automatically detect and use all available processors.
verbose	Logical indicating whether to display progress.
...	Additional arguments to be passed directly to ConsensusSequence for an AAStringSet, DNAStringSet, or RNAStringSet, or to consensusString for a BStringSet.

Details

Creates a consensus sequence for each of the distinct groups defined in colName. The resulting XStringSet contains as many consensus sequences as there are distinct groups in colName. For example, it is possible to create a set of consensus sequences with one consensus sequence for each "id" in the tblName.

Value

An XStringSet object containing the consensus sequence for each group. The names of the XStringSet contain the number of sequences and name of each group.

IdentifyByRank *Identify By Taxonomic Rank*

Description

Identifies sequences by a specific level of their taxonomic rank.

Usage

```
IdentifyByRank(dbFile,
               tblName = "Seqs",
               level = 0,
               add2tbl = FALSE,
               verbose = TRUE)
```

Arguments

dbFile	A SQLite connection object or a character string specifying the path to the database file.
tblName	Character string specifying the table where the rank information is located.
level	Level of the taxonomic rank. (See details section below.)
add2tbl	Logical or a character string specifying the table name in which to add the result.
verbose	Logical indicating whether to print database queries and other information.

Details

IdentifyByRank simply identifies a sequence by a specific level of its taxonomic rank. Requires that rank information be present in the `tblName`, such as that created by default when importing sequences from a GenBank formatted file.

The input parameter `level` should be an integer giving the “level” of the taxonomic rank to choose as the identifier. Negative levels are interpreted as being that many levels from the last level in each rank. The level zero selects the base level (see below).

If the specified level of rank does not exist then the closest rank is chosen. Therefore, setting `level` to `Inf` will always select the last taxonomic level (i.e., genus).

For example, a representative “rank” imported from a GenBank file is:

```
Saccharomyces cerevisiae
Eukaryota; Fungi; Ascomycota; Saccharomycotina; Saccharomycetes;
Saccharomycetales; Saccharomycetaceae; Saccharomyces.
```

Setting `level` to 0 would result in an identifier of “Saccharomyces cerevisiae”, because it is on the first line. A `level` of 2 would return “Fungi”, and -2 (second to last) would return “Saccharomycetaceae”. A `level` of `Inf` would find the nearest level to the end, “Saccharomyces”.

Value

A data.frame with the rank and corresponding identifier as `identifier`. Note that quotes are stripped from identifiers to prevent problems that they may cause. The `origin` gives the rank preceding the identifier. If `add2tbl` is not `FALSE` then the “identifier” column is updated in `dbFile`.

```

IdLengths	<i>Determine the Number of Bases, Nonbases, and Width of Each Sequence</i>
-----------	--

Description

Counts the number of bases (A, C, G, T) and ambiguities/degeneracies in each sequence.

Usage

```
IdLengths(dbFile,
          tblName = "Seqs",
          identifier = "",
          type = "DNAStringSet",
          add2tbl = FALSE,
          batchSize = 10000,
          processors = 1,
          verbose = TRUE)
```

Arguments

dbFile	A SQLite connection object or a character string specifying the path to the database file.
tblName	Character string specifying the table where the sequences are located.
identifier	Optional character string used to narrow the search results to those matching a specific identifier. If "" then all identifiers are selected.
type	The type of XStringSet being processed. This should be (an abbreviation of) one of "DNAStringSet" or "RNAStringSet".
add2tbl	Logical or a character string specifying the table name in which to add the result.
batchSize	Integer specifying the number of sequences to process at a time.
processors	The number of processors to use, or NULL to automatically detect and use all available processors.
verbose	Logical indicating whether to display progress.

Value

A data.frame with the number of bases (“A”, “C”, “G”, or “T”), nonbases, and width of each sequence. The width is defined as the sum of bases and nonbases in each sequence. The row.names of the data.frame correspond to the "row_names" in the tblName of the dbFile.

IdTaxa

Assign Sequences a Taxonomic Classification

Description

Classifies sequences according to a training set by assigning a confidence to taxonomic labels for each taxonomic rank.

Usage

```
IdTaxa(test,
        trainingSet,
        type = "extended",
        strand = "both",
        threshold = 60,
        bootstraps = 100,
        samples = L^0.47,
        minDescend = 0.98,
        processors = 1,
        verbose = TRUE)
```

Arguments

test	A DNAStrngSet or RNAStrngSet of unaligned sequences.
trainingSet	An object of class Taxa and subclass Train.
type	Character string indicating the type of output desired. This should be (an abbreviation of) one of "extended" or "collapsed". (See value section below.)

strand	Character string indicating the orientation of the test sequences relative to the trainingSet. This should be (an abbreviation of) one of "both", "top", or "bottom". The top strand is defined as the input test sequences being in the same orientation as the trainingSet, and the bottom strand is its reverse complement orientation. The default of "both" will classify using both orientations and choose the result with highest confidence. Choosing the correct strand will make classification over 2-fold faster, assuming that all of the reads are in the same orientation.
threshold	Numeric specifying the confidence at which to truncate the output taxonomic classifications. Lower values of threshold will classify deeper into the taxonomic tree at the expense of accuracy, and vice-versa for higher values of threshold.
bootstraps	Integer giving the number of bootstrap replicates to perform for each sequence.
samples	A function or call written as a function of 'L', which will evaluate to a numeric vector the same length as 'L'. Typically of the form "A + B*L^C", where 'A', 'B', and 'C' are constants.
minDescend	Numeric giving the minimum fraction of bootstraps required to descend the tree during the initial tree descend phase of the algorithm. Higher values are less likely to descend the tree, causing direct comparison against more sequences in the trainingSet. Lower values may increase classification speed at the expense of accuracy. Suggested values are between 1.0 and 0.9.
processors	The number of processors to use, or NULL to automatically detect and use all available processors.
verbose	Logical indicating whether to display progress.

Details

Sequences in test are each assigned a taxonomic classification based on the trainingSet created with [LearnTaxa](#). Each taxonomic level is given a confidence between 0% and 100%, and the taxonomy is truncated where confidence drops below threshold. If the taxonomic classification was truncated, the last group is labeled with "unclassified_" followed by the final taxon's name. Note that the reported confidence is not a p-value but does directly relate to a given classification's probability of being wrong. The default threshold of 60% is intended to minimize the rate of incorrect classifications. Lower values of threshold (e.g., 50%) may be preferred to increase the taxonomic depth of classifications.

Value

If type is "extended" (the default) then an object of class Taxa and subclass Train is returned. This is stored as a list with elements corresponding to their respective sequence in test. Each list element contains components:

taxon	A character vector containing the taxa to which the sequence was assigned.
confidence	A numeric vector giving the corresponding percent confidence for each taxon.
rank	If the classifier was trained with a set of ranks, a character vector containing the rank name of each taxon.

If type is "collapsed" then a character vector is returned with the taxonomic assignment for each sequence. This takes the repeating form "Taxon name [rank, confidence%]; ..." if ranks were supplied during training, or "Taxon name [confidence%]; ..." otherwise.

LearnTaxa

Train a Classifier for Assigning Taxonomy

Description

Trains a classifier based on a reference taxonomy containing sequence representatives assigned to taxonomic groups.

Usage

```
LearnTaxa(train,
           taxonomy,
           rank = NULL,
           K = floor(log(100*quantile(width(train), 0.99), 4)),
           minFraction = 0.01,
           maxFraction = 0.06,
           maxIterations = 10,
           multiplier = 100,
           maxChildren = 200,
           verbose = TRUE)
```

Arguments

<code>train</code>	A DNASTringSet or RNASTringSet of unaligned sequences.
<code>taxonomy</code>	Character string providing the reference taxonomic assignment for each sequence in <code>train</code> . Taxonomic ranks are separated by semicolons (“;”) beginning with “Root”.
<code>rank</code>	Optionally, a <code>data.frame</code> with 5 named columns giving the “Index” (i.e., 0 to the number of unique taxa), “Name” (i.e., taxon name), “Parent” (i.e., “Index” of the parent taxon), “Level” (i.e., integer rank level), and “Rank” (e.g., “genus”) of each taxonomic rank. This information is often provided in a separate “taxid” file along with publicly available training sequence sets.
<code>K</code>	Integer specifying the k-mer size. The default value of <code>K</code> is such that k-mer matches between sequences are rarely (~1%) found by chance.
<code>minFraction</code>	Numeric giving the minimum fraction of k-mers to sample during the initial tree descent phase of the classification algorithm. (See details section below.)
<code>maxFraction</code>	Numeric giving the maximum fraction of k-mers to sample during the initial tree descent phase of the classification algorithm. (See details section below.)
<code>maxIterations</code>	Integer specifying the maximum number of iterations to attempt re-classification of a training sequence before declaring it a “problem sequence”. (See details section below.)
<code>multiplier</code>	Numeric indicating the degree to which individual sequences have control over the fraction of k-mers sampled at any edge during the initial tree descent phase of the classification algorithm. (See details section below.)
<code>maxChildren</code>	Integer giving the maximum number of child taxa of any taxon at which to consider further descending the taxonomic tree. A value of 1 will prevent use of the tree descent algorithm altogether. Lower values may decrease classification speed, but result in output objects that require less memory.
<code>verbose</code>	Logical indicating whether to display progress.

Details

Learning about the training data is a two part process consisting of (i) forming a taxonomic tree and then (ii) ensuring that the training sequences can be correctly reclassified. The latter step relies on reclassifying the sequences in `train` by descending the taxonomic tree, a process termed “tree descent”. Ultimately, the goal of tree descent is to quickly and accurately narrow the selection of groups where a sequence may belong. During the learning process, tree descent is tuned so that it performs well when classifying new sequences.

The process of training the classifier first involves learning the taxonomic tree spanning all of the reference sequences in `train`. Typically, reference taxonomic classifications are provided by an authoritative source, oftentimes along with a “taxid” file containing taxonomic rank information. The taxonomic tree may contain any number of levels (e.g., Root, Phylum, Class, Order, Family, Genus) as long as they are hierarchically nested and always begin with “Root”.

The second phase of training the classifier, tree descent, involves learning the optimal set of k-mers for discerning between the different sub-groups under each edge. Here a fraction of the k-mers with the greatest discerning power are matched to a training sequence, and this process is repeated with 100 random subsamples to decide on the set of possible taxonomic groups to which a training sequence may belong.

The learning process works by attempting to correctly re-classify each training sequence in the `taxonomy`. Initially, `maxFraction` of informative k-mers are repeatedly sampled at each edge during

tree descent. Training sequences that are incorrectly classified at an edge will lower the fraction of k-mers that are sampled by an amount that is proportional to `multiplier`. As the fraction of sampled k-mers decreases, the tree descent process terminates at higher rank levels.

A major advantage of tree descent is that it both speeds up the classification process and indicates where the training set likely contains mislabeled sequences or incorrectly-placed taxonomic groups. Training sequences that are not correctly classified within `maxIterations` are marked as “problem sequences”, because it is likely that they are mislabeled. If enough sequences have difficulty being correctly classified at an edge that the fraction drops below `minFraction`, then the edge is recorded as a “problem group”.

The final result is an object that can be used for classification with `IdTaxa`, as well as information about `train` that could be used to help correct any errors in the taxonomy.

Value

An object of class `Taxa` and subclass `Train`, which is stored as a list with components:

<code>taxonomy</code>	A character vector containing all possible groups in the taxonomy.
<code>taxa</code>	A character vector containing the basal taxon in each taxonomy.
<code>ranks</code>	A character vector of rank names for each taxon, or <code>NULL</code> if rank information was not supplied.
<code>levels</code>	Integer giving the rank level of each taxon.
<code>children</code>	A list containing the index of all children in the taxonomy for each taxon.
<code>parents</code>	An integer providing the index of the parent for each taxon.
<code>fraction</code>	A numeric between <code>minFraction</code> and <code>maxFraction</code> that represents the learned fraction of informative k-mers to sample for each taxon during the initial tree descent phase of the classification algorithm. Problem groups are marked by a fraction of <code>NA</code> .
<code>sequences</code>	List containing the integer indices of sequences in <code>train</code> belonging to each taxon.
<code>kmers</code>	List containing the unique sorted k-mers (converted to integers) belonging to each sequence in <code>train</code> .
<code>crossIndex</code>	Integer indicating the index in taxonomy of each sequence’s taxonomic label.
<code>K</code>	The value of <code>K</code> provided as input.
<code>IDFweights</code>	Numeric vector of length 4^K providing the inverse document frequency weight for each k-mer.
<code>decisionKmers</code>	List of informative k-mers and their associated relative frequencies for each internal edge in the taxonomy.
<code>problemSequences</code>	A <code>data.frame</code> providing the “Index”, “Expected” label, and “Predicted” taxon for sequences that could not be correctly classified during the initial tree descent phase of the algorithm.
<code>problemGroups</code>	Character vector containing any taxonomic groups that repeatedly had problems with correctly re-classifying sequences in <code>train</code> during the initial tree descent phase of the classification algorithm. Problem groups likely indicate that a number of the sequences (or an entire group of sequences) assigned to the problem group are incorrectly placed in the taxonomic tree.

MaskAlignment

Mask Highly Variable Regions of An Alignment

Description

Automatically masks poorly aligned regions of an alignment based on sequence conservation and gap frequency.

Usage

```
MaskAlignment(myXStringSet,
              type = "sequences",
              windowSize = 5,
              threshold = 1,
              maxFractionGaps = 0.2,
              includeTerminalGaps = FALSE,
              correction = FALSE,
              showPlot = FALSE)
```

Arguments

`myXStringSet` An `AAStringSet`, `DNAStrngSet`, or `RNAStringSet` object of aligned sequences.

`type` Character string indicating the type of result desired. This should be (an abbreviation of) one of "sequences", "ranges", or "values". (See value section below.)

windowSize	Integer value specifying the size of the region to the left and right of the center-point to use in calculating the moving average.
threshold	Numeric giving the average entropy in bits below which a region is masked.
maxFractionGaps	Numeric specifying the maximum fraction of gaps in an alignment column to be masked.
includeTerminalGaps	Logical specifying whether or not to include terminal gaps ("." or "-" characters on each end of the sequences) into the calculation of gap fraction.
correction	Logical indicating whether to apply a small-sample size correction to columns with few letters (Yu et al., 2015).
showPlot	Logical specifying whether or not to show a plot of the positions that were kept or masked.

Details

Poorly aligned regions of a multiple sequence alignment may lead to incorrect results in downstream analyses. One method to mitigate their effects is to mask columns of the alignment that may be poorly aligned, such as highly-variable regions or regions with many insertions and deletions (gaps).

Highly variable regions are detected by their signature of having a low information content. Here, information content is defined by the relative entropy of a column in the alignment (Yu et al., 2015), which is higher for conserved columns. The relative entropy is based on the background distribution of letter-frequencies in the alignment.

A moving average of windowSize nucleotides to the left and right of the center-point is applied to smooth noise in the information content signal along the sequence. Regions dropping below threshold bits or more than maxFractionGaps are masked.

Value

If type is "sequences" then a MultipleAlignment object of the input type with masked columns where the input criteria are met. Otherwise, if type is "ranges" then an IRanges object giving the start and end positions of the masked columns. Else (type is "values") a data.frame containing one row per site in the alignment and three columns of information:

"entropy"	The entropy score of each column, in units of bits.
"gaps"	For each column, the fraction of gap characters ("-" or ".").
"mask"	A logical vector indicating whether or not the column met the criteria for masking.

MeltDNA

Simulate Melting of DNA

Description

The denaturation of double-stranded DNA occurs over a range of temperatures. Beginning from a helical state, DNA will transition to a random-coil state as temperature is increased. MeltDNA predicts the positional helicity, melt curve, or its negative derivate at different temperatures.

Usage

```

MeltDNA(myDNAStringSet,
        type = "derivative",
        temps = 50:100,
        ions = 0.2)

```

Arguments

myDNAStringSet A DNAStringSet object or character vector with one or more sequences in 5' to 3' orientation.

type Character string indicating the type of results desired. This should be (an abbreviation of) one of "derivative curves", "melt curves", or "positional probabilities".

temps	Numeric vector of temperatures (in degrees Celsius).
ions	Numeric giving the molar sodium equivalent ionic concentration. Values must be at least 0.01M.

Details

When designing a high resolution melt (HRM) assay, it is useful to be able to predict the results before performing the experiment. Multi-state models of DNA melting can provide near-qualitative agreement with experimental DNA melt curves obtained with quantitative PCR (qPCR). MeltDNA employs the algorithm of Tostesen et al. (2003) with an approximation for loop entropy that runs in nearly linear time and memory, which allows very long DNA sequences (up to 100,000 base pairs) to be analyzed.

Denaturation is a highly cooperative process whereby regions of double-stranded DNA tend to melt together. For short sequences (< 100 base pairs) there is typically a single transition from a helical to random-coil state. Longer sequences may exhibit more complex melting behavior with multiple peaks, as domains of the DNA melt at different temperatures. The melting curve represents the average fractional helicity (Theta) at each temperature, and can be used for genotyping with high resolution melt analysis.

Value

MeltDNA can return three types of results: positional helicity, melting curves, or the negative derivative of the melting curves. If type is "position", then a list is returned with one component for each sequence in myDNAStringSet. Each list component contains a matrix with the probability of helicity (Theta) at each temperature (rows) and every position in the sequence (columns).

If type is "melt", then a matrix with the average Theta across the entire sequence is returned. This matrix has a row for each input temperature (temps), and a column for each sequence in myDNAStringSet. For example, the value in element [3,4] is the average helicity of the fourth input sequence at the third input temperature. If type is "derivative" then the values in the matrix are the derivative of the melt curve at each temperature.

Note

MeltDNA uses nearest neighbor parameters from SantaLucia (1998).

MODELS

Available Models of DNA Evolution

Description

The MODELS character vector contains the models of DNA evolution that can be used by `IdClusters`.

Usage

```
MODELS
```

Details

Six models of DNA evolution are available, with or without the discrete Gamma rates distribution. These are described in order of increasing number of parameters as follows:

JC69 (Jukes and Cantor, 1969) The simplest substitution model that assumes equal base frequencies (1/4) and equal mutation rates.

K80 (Kimura, 1980) Assumes equal base frequencies, but distinguishes between the rate of transitions and transversions.

T92 (Tamura, 1992) In addition to distinguishing between transitions and transversions, a parameter is added to represent G+C content bias.

F81 (Felsenstein, 1981) Assumes equal mutation rates, but allows all bases to have different frequencies.

HKY85 (Hasegawa, Kishino and Yano, 1985) Distinguishes transitions from transversions and allows bases to have different frequencies.

TN93 (Tamura and Nei, 1993) Allows for unequal base frequencies and distinguishes between transversions and the two possible types of transitions (i.e., A <-> G & C <-> T).

+G (Yang, 1993) Specifying a model+G4 adds a single parameter to any of the above models to relax the assumption of equal rates among sites in the DNA sequence. The single parameter specifies the shape of the Gamma Distribution. The continuous distribution is represented with 2-10 discrete rates and their respective probabilities as determined by the Laguerre Quadrature method (Felsenstein, 2001). For example, specifying a model+G8 would represent the continuous Gamma Distribution with eight rates and their associated probabilities.

MODELS

NNLS

Sequential Coordinate-wise Algorithm for the Non-negative Least Squares Problem

Description

Consider the linear system $Ax = b$ where $A \in R^{m \times n}$, $x \in R^n$, and $b \in R^m$. The technique of least squares proposes to compute x so that the sum of squared residuals is minimized. NNLS solves the least squares problem $\min \|Ax = b\|^2$ subject to the constraint $x \geq 0$. This implementation of the Sequential Coordinate-wise Algorithm uses a sparse input matrix A , which makes it efficient for large sparse problems.

Usage

```

NNLS(A,
      b,
      precision = sqrt(.Machine$double.eps),
      processors = 1,
      verbose = TRUE)

```

Arguments

<code>A</code>	List representing the sparse matrix with integer components <code>i</code> and <code>j</code> , numeric component <code>x</code> . The fourth component, <code>dimnames</code> , is a list of two components that contains the names for every row (component 1) and column (component 2).
<code>b</code>	Numeric matrix for the set of observed values. (See details section below.)
<code>precision</code>	The desired accuracy.
<code>processors</code>	The number of processors to use, or NULL to automatically detect and use all available processors.
<code>verbose</code>	Logical indicating whether to display progress.

Details

The input `b` can be either a matrix or a vector of numerics. If it is a matrix then it is assumed that each column contains a set of observations, and the output `x` will have the same number of columns. This allows multiple NNLS problems using the same `A` matrix to be solved simultaneously, and greatly accelerates computation relative to solving each sequentially.

Value

A list of two components:

<code>x</code>	The matrix of non-negative values that best explains the observed values given by <code>b</code> .
<code>res</code>	A matrix of residuals given by $Ax - b$.

```

OrientNucleotides *Orient Nucleotide Sequences*

Description

Orients nucleotide sequences to match the directionality and complementarity of specified reference sequences.

Usage

```
OrientNucleotides(myXStringSet,
                  reference = which.max(width(myXStringSet)),
                  type = "sequences",
                  orientation = "all",
                  threshold = 0.05,
                  verbose = TRUE,
                  processors = 1)
```

Arguments

myXStringSet	A DNASTringSet or RNASTringSet of unaligned sequences.
reference	The index of reference sequences with the same (desired) orientation. By default the first sequence with maximum width will be used.
type	Character string indicating the type of results desired. This should be (an abbreviation of) either "sequences", "orientations", or "both".
orientation	Character string(s) indicating the allowed reorientation(s) of non-reference sequences. This should be (an abbreviation of) either "all", "reverse", "complement", and/or "both" (for reverse complement).
threshold	Numeric giving the decrease in k-mer distance required to adopt the alternative orientation.
verbose	Logical indicating whether to display progress.
processors	The number of processors to use, or NULL to automatically detect and use all available processors.

Details

Biological sequences can sometimes have inconsistent orientation that interferes with their analysis. OrientNucleotides will reorient sequences by changing their directionality and/or complementarity to match specified reference sequences in the same set. The process works by finding the k-mer distance between the reference sequence(s) and each allowed orientation of the sequences. Alternative orientations that lessen the distance by at least threshold are adopted. Note that this procedure requires a moderately similar reference sequence be available for each sequence that needs to be reoriented. Sequences for which a corresponding reference is unavailable will most likely be left alone because alternative orientations will not pass the threshold. For this reason, it is recommended to specify several markedly different sequences as references.

Value

`OrientNucleotides` can return two types of results: the relative orientations of sequences and/or the reoriented sequences. If `type` is "sequences" (the default) then the reoriented sequences are returned. If `type` is "orientations" then a character vector is returned that specifies whether sequences were reversed ("r"), complemented ("c"), reversed complemented ("rc"), or in the same orientation ("") as the reference sequences (marked by NA). If `type` is "both" then the output is a list with the first component containing the "orientations" and the second component containing the "sequences".

PFASUM

PFASUM Amino Acid Substitution Matrices

Description

The PFASUM amino acid substitution matrices defined by Keul, F., et al. (2017).

Usage

```
data("PFASUM")
```

Format

The format is: num [1:25, 1:25, 1:90] 0.9492 -1.7337 0.2764 1.8153 0.0364 ... - attr(*, "dim-names")=List of 3 ..\$: chr [1:25] "A" "R" "N" "D"\$: chr [1:25] "A" "R" "N" "D"\$: chr [1:90] "11" "12" "13" "14" ...

Details

Substitution matrix values represent the log-odds of observing an aligned pair of amino acids versus the likelihood of finding the pair by chance. The PFASUM substitution matrices are stored as an array named by each sub-matrix's similarity threshold. (See examples section below.) In all cases values are in units of third-bits ($\log(\text{odds ratio}) * 3/\log(2)$).

PredictDBN

Predict RNA Secondary Structure in Dot-Bracket Notation

Description

Predicts a consensus RNA secondary structure from a multiple sequence alignment using mutual information.

Usage

```
PredictDBN(myXStringSet,
           type = "states",
           minOccupancy = 0.5,
           impact = c(1, 1.2, 0.4, -1),
           avgProdCorr = 1,
           slope = 2,
           shift = 1.3,
           threshold = 0.7,
           pseudoknots = 1,
           weight = NA,
           processors = 1,
           verbose = TRUE)
```

Arguments

myXStringSet	A DNASTringSet or RNASTringSet object containing aligned sequences.
type	Character string indicating the type of results desired. This should be (an unambiguous abbreviation of) one of "states", "pairs", "evidence", "scores", "structures", or "search". (See value section below.)

minOccupancy	Numeric specifying the minimum occupancy (1 - fraction of gaps) required to include a column of the alignment in the prediction.
impact	A vector with four elements giving the weights of A/U, G/C, G/U, and other pairings, respectively. The last element of impact is the penalty for pairings that are inconsistent with two positions being paired (e.g., A/- or A/C).
avgProdCorr	Numeric specifying the weight of the average product correction (APC) term, as described in Buslje et al. (2009).
slope	Numeric giving the slope of the sigmoid used to convert mutual information values to scores ranging from zero to one.
shift	Numeric giving the relative shift of the sigmoid used to convert mutual information values to scores ranging from zero to one.
threshold	Numeric specifying the score threshold at which to consider positions for pairing. Only applicable if type is "states" or "pairs".
pseudoknots	Integer indicating the maximum order of pseudoknots that are acceptable. A value of 0 will prevent pseudoknots in the structure, whereas 1 (the default) will search for first-order pseudoknots. Only used if type is "states" or "pairs".
weight	Either a numeric vector of weights for each sequence, a single number implying equal weights, or NA (the default) to automatically calculate sequence weights based on myXStringSet.
processors	The number of processors to use, or NULL to automatically detect and use all available processors.
verbose	Logical indicating whether to display progress.

Details

PredictDBN employs an extension of the method described by Freyhult et al. (2005) for determining a consensus RNA secondary structure. It uses the mutual information (H) measure to find covarying positions in a multiple sequence alignment. The original method is modified by the addition of different weights for each type of base pairing and each input sequence. The formula for mutual information between positions i and j then becomes:

$$H(i, j) = \sum_{XY \in bp} \left(impact(XY) \cdot f_{i,j}(XY) \cdot \log_2 \left(\frac{f_{i,j}(XY)}{f_i(X) \cdot f_j(Y)} \right) \right)$$

where, bp denotes the base pairings A/U, C/G, and G/U; $impact$ is their weight; f is the frequency of single bases or pairs weighted by the corresponding weight of each sequence.

A penalty is then added for bases that are inconsistent with pairing:

$$H_{mod}(i, j) = H(i, j) + \sum_{XY \notin bp} \left(impact(XY) \cdot f_{i,j}(XY) \right)$$

Next an average product correction (Buslje et al., 2009) is applied to the matrix H :

$$H_{APC}(i, j) = H_{mod}(i, j) - avgProdCorr \cdot \frac{\overline{H_{mod}(i, \cdot)} \cdot \overline{H_{mod}(\cdot, j)}}{\overline{H_{mod}(\cdot, \cdot)}}$$

The mutual information values are then rescaled between 0 and 1 by applying a sigmoidal transformation, which is controlled by $shift$ and $slope$:

$$H_{final}(i, j) = \left(1 + \exp \left(slope \cdot \log_e \left(\frac{H_{APC}(i, j)}{shift \cdot H_{APC}[n]} \right) \right) \right)^{-1}$$

where, n is the number of positions having `minOccupancy` divided by two (i.e., the maximum possible number of paired positions) and $H_{APC}[n]$ denotes the n^{th} highest value in the matrix H_{APC} .

If type is "states" or "pairs", the secondary structure is determined using a variant of the Nussinov algorithm similar to that described by Venkatachalam et al. (2014). Pairings with a score below `threshold` are not considered during the traceback. If `psuedoknots` is greater than 0, paired positions are removed from consideration and the method is applied again to find pseudoknots.

In practice the secondary structure prediction is most accurate when the input alignment is of high quality, contains a wide diversity of sequences, the number of sequences is large, no regions are completely conserved across all sequences, and most of the sequences span the entire alignment (i.e., there are few partial/incomplete sequences).

Value

If type is "states" (the default), then the output is a character vector with the predicted secondary structure assignment for each position in `myXStringSet`. Standard dot-bracket notation (DBN) is used, where "." signifies an unpaired position, "(" and ")" a paired position, and successive "[]", "{", and "<>" indicate increasing order pseudoknots. Columns below `minOccupancy` are denoted by the "-" character to indicate that they contained too many gaps to be included in the consensus structure.

If type is "pairs", then a matrix is returned with one row for each base pairing and three columns giving the positions of the paired bases and their pseudoknot order.

If type is "evidence", then a matrix is returned with one row for each base pairing and three columns giving the positions of the paired bases and their respective scores (greater than or equal to `threshold`). This differs from type "pairs" in that "evidence" does not perform a traceback. Therefore, it is possible to have conflicting evidence where a single base has evidence for pairing with multiple other bases.

If type is "scores", then a matrix of three rows is returned, where the values in a column represent the maximum score for a state in each position. Columns sum to 1 if the position was above `minOccupancy` and 0 otherwise.

If type is "structures", then the output is a list with one element for each sequence in `myXStringSet`. Each list element contains a matrix of dimension 3 (each state) by the number of nucleotides in the sequence. Columns of the matrix sum to zero where the nucleotide was located in a position that was below `minOccupancy`. Otherwise, positions are considered paired if they are consistent with pairing (i.e., A/U, C/G, or G/U) in the consensus secondary structure.

If type is "search" then an attempt is made to find additional secondary structure beyond positions exhibiting covariation. First, anchors are identified as pairs of covarying positions with their score above `threshold`. Next, the regions between anchors are searched for previously unidentified stem loops. Finally, any helices are assigned a score according to their length, i.e. one minus the probability of finding that many consecutive pairs within the anchor boundaries by chance. Hence, output type "search" will find secondary structure outside of the consensus structure shared by most sequences, and can identify secondary structure in conserved alignment regions.

 PredictHEC

Predict Protein Secondary Structure as Helix, Beta-Sheet, or Coil

Description

Predicts 3-state protein secondary structure based on the primary (amino acid) sequence using the GOR IV method (Garnier et al., 1996).

Usage

```
PredictHEC(myAAStringSet,
           type = "states",
           windowSize = 7,
           background = c(H = -0.12, E = -0.25, C = 0.23),
           HEC_MI1 = NULL,
           HEC_MI2 = NULL)
```

Arguments

myAAStringSet	An AAStringSet object of sequences.
type	Character string indicating the type of results desired. This should be (an unambiguous abbreviation of) one of "states", "scores", or "probabilities".
windowSize	Numeric specifying the number of residues to the left or right of the center position to use in the prediction.
background	Numeric vector with the background "scores" for each of the three states (H, E, and C).
HEC_MI1	An array of dimensions 20 x 21 x 3 giving the mutual information for single residues.
HEC_MI2	An array of dimensions 20 x 20 x 21 x 21 x 3 giving the mutual information for pairs of residues.

Details

The GOR (Garnier-Osguthorpe-Robson) method is an information-theory method for prediction of secondary structure based on the primary sequence of a protein. Version IV of the method makes 3-state predictions based on the mutual information contained in single residues and pairs of residues within windowSize residues of the position being assigned. This approach is about 65% accurate, and is one of the most accurate methods for assigning secondary structure that only use a single sequence. This implementation of GOR IV does not use decision constants or the number of contiguous states when assigning the final state. Note that characters other than the standard 20 amino acids are not assigned a state.

Value

If type is "states" (the default), then the output is a character vector with the secondary structure assignment ("H", "E", or "C") for each residue in myAAStringSet.

Otherwise, the output is a list with one element for each sequence in myAAStringSet. Each list element contains a matrix of dimension 3 (H, E, or C) by the number of residues in the sequence. If type is "scores", then values in the matrix represent log-odds "scores". If type is "probabilities" then the values represent the normalized probabilities of the three states at a position.

ReadDendrogram

Read a Dendrogram from a Newick Formatted File

Description

Reads a dendrogram object from a file in Newick (also known as New Hampshire) parenthetic format.

Usage

```
ReadDendrogram(file,
                convertBlanks = TRUE,
                internalLabels = TRUE,
                keepRoot = TRUE)
```

Arguments

file	a connection object or a character string.
convertBlanks	Logical specifying whether to convert underscores in unquoted leaf labels to spaces.
internalLabels	Logical indicating whether to keep internal node labels as “edgetext” preceding the node in the dendrogram.
keepRoot	Logical specifying whether to keep the root node (if one is present) as a dendrogram leaf.

Details

ReadDendrogram will create a dendrogram object from a Newick formatted tree. Note that all edge lengths must be specified, but labels are optional.

Value

An object of class dendrogram.

```

RemoveGaps*Remove Gap Characters in Sequences*

Description

Removes gaps ("- or "." characters) in a set of sequences, either deleting all gaps or only those shared by all sequences in the set.

Usage

```
RemoveGaps(myXStringSet,  
           removeGaps = "all",  
           processors = 1)
```

Arguments

<code>myXStringSet</code>	An <code>AAStringSet</code> , <code>DNAStrngSet</code> , or <code>RNAStringSet</code> object containing sequences.
<code>removeGaps</code>	Determines how gaps ("- or "." characters) are removed in the sequences. This should be (an unambiguous abbreviation of) one of "none", "all" or "common".
<code>processors</code>	The number of processors to use, or <code>NULL</code> to automatically detect and use all available processors.

Details

The `removeGaps` argument controls which gaps are removed in `myXStringSet`. Setting `removeGaps` to "all" will remove all gaps in the input sequences, whereas setting `removeGaps` to "common" will remove only gaps that exist in the same position in every sequence. Therefore, the latter method will leave gaps in place that are not shared by every sequence, requiring that the sequences in `myXStringSet` all be the same length (i.e., be aligned). Setting `removeGaps` to "none" will simply return `myXStringSet` unaltered.

Value

An `XStringSet` of the same type as `myXStringSet`.

RESTRICTION_ENZYMES *Common Restriction Enzyme's Cut Sites*

Description

A character vector of common restriction sites named by the restriction enzyme that cuts at each site. Sequence specificity is listed in 5' to 3' orientation based on the IUPAC_CODE_MAP. The cut site is either signified by a “/” for palindromic sites, or two numbers giving the position of the top and bottom cut positions relative to the site's 3'-end.

Usage

```
data(RESTRICTION_ENZYMES)
```

Format

The format is: Named chr [1:224] "GACGT/C" "G/GTACC" "GT/MKAC" ... - attr(*, "names")= chr [1:224] "AatII" "Acc65I" "AccI" "AciI" ...

Source

Restriction enzymes sold by [New England BioLabs](#).

Examples

```
data(RESTRICTION_ENZYMES)

SearchDB *Obtain Specific Sequences from a Database*

Description

Returns the set of sequences meeting the search criteria.

Usage

```
SearchDB(dbFile,
         tblName = "Seqs",
         identifier = "",
         type = "XStringSet",
         limit = -1,
         replaceChar = NA,
         nameBy = "row_names",
         orderBy = "row_names",
         countOnly = FALSE,
         removeGaps = "none",
         quality = "Phred",
         clause = "",
         processors = 1,
         verbose = TRUE)
```

Arguments

dbFile	A SQLite connection object or a character string specifying the path to the database file.
tblName	Character string specifying the table where the sequences are located.
identifier	Optional character string used to narrow the search results to those matching a specific identifier. If "" (the default) then all identifiers are selected.
type	The type of XStringSet (sequences) to return. This should be (an unambiguous abbreviation of) one of "XStringSet", "DNAStrngSet", "RNAStrngSet", "AAStringSet", "BStringSet", "QualityScaledXStringSet", "QualityScaledDNAStrngSet", "QualityScaledRNAStrngSet", "QualityScaledAAStringSet", or "QualityScaledBStringSet". If type is "XStringSet" or "QualityScaledXStringSet" then an attempt is made to guess the type of sequences based on their composition.
limit	Number of results to display. The default (-1) does not limit the number of results.
replaceChar	Optional character used to replace any characters of the sequence that are not present in the XStringSet's alphabet. Not applicable if type=="BStringSet". The default (NA) results in an error if an incompatible character exist. (See details section below.)
nameBy	Character string giving the column name for naming the XStringSet.
orderBy	Character string giving the column name for sorting the results. Defaults to the order of entries in the database. Optionally can be followed by "ASC" or "DESC" to specify ascending (the default) or descending order.
countOnly	Logical specifying whether to return only the number of sequences.
removeGaps	Determines how gaps ("- or ." characters) are removed in the sequences. This should be (an unambiguous abbreviation of) one of "none", "all" or "common".
clause	An optional character string to append to the query as part of a "where clause".
quality	The type of quality object to return if type is a QualityScaledXStringSet. This should be (an unambiguous abbreviation of) one of "Phred", "Solexa", or "Illumina". Note that recent versions of Illumina software provide "Phred" formatted quality scores.
processors	The number of processors to use, or NULL to automatically detect and use all available processors.
verbose	Logical indicating whether to display queries as they are sent to the database.

Details

If type is "DNAStrngSet" then all U's are converted to T's before creating the DNAStrngSet, and vice-versa if type is "RNAStrngSet". All remaining characters not in the XStringSet's alphabet are converted to replaceChar or removed if replaceChar is "". Note that if replaceChar is NA (the default), it will result in an error when an unexpected character is found. Quality information is interpreted as PredQuality scores.

Value

An XStringSet or QualityScaledXStringSet with the sequences that meet the specified criteria. The names of the object correspond to the value in the nameBy column of the database.

```

Seqs2DB

Add Sequences from Text File to Database

Description

Adds sequences to a database.

Usage

```
Seqs2DB(seqs,
        type,
        dbFile,
        identifier,
        tblName = "Seqs",
        chunkSize = 1e7,
        replaceTbl = FALSE,
        fields = c(accession = "ACCESSION", rank = "ORGANISM"),
        processors = 1,
        verbose = TRUE,
        ...)
```

Arguments

seqs A connection object or a character string specifying the file path to the file containing the sequences, an XStringSet object if type is XStringSet, or a QualityScaledXStringSet object if type is QualityScaledXStringSet. Files compressed with gzip, bzip2, xz, or lzma compression are automatically detected and decompressed during import. Full URL paths (e.g., "http://" or "ftp://") to uncompressed text files or gzip compressed text files can also be used.

<code>type</code>	The type of the sequences (<code>seqs</code>) being imported. This should be (an unambiguous abbreviation of) one of "FASTA", "FASTQ", "GenBank", "XStringSet", or "QualityScaledXStringSet".
<code>dbFile</code>	A SQLite connection object or a character string specifying the path to the database file. If the <code>dbFile</code> does not exist then a new database is created at this location.
<code>identifier</code>	Character string specifying the "id" to give the imported sequences in the database.
<code>tblName</code>	Character string specifying the table in which to add the sequences.
<code>chunkSize</code>	Number of characters to read at a time.
<code>replaceTbl</code>	Logical indicating whether to overwrite the entire table in the database. If FALSE (the default) then the sequences are appended to any already existing in the <code>tblName</code> . If TRUE the entire table is dropped, removing any existing sequences before adding any new sequences.
<code>fields</code>	Named character vector providing the fields to import from a "GenBank" formatted file as text columns in the database (not applicable for other "type"s). The default is to import the "ACCESSION" field as a column named "accession" and the "ORGANISM" field as a column named "rank". Other uppercase fields, such as "LOCUS" or "VERSION", can be specified in similar manner. Note that the "DEFINITION" field is automatically imported as a column named "description" in the database.
<code>processors</code>	The number of processors to use, or NULL to automatically detect and use all available processors.
<code>verbose</code>	Logical indicating whether to display each query as it is sent to the database.
<code>...</code>	Further arguments to be passed directly to Codec for compressing sequence information.

Details

Sequences are imported into the database in chunks of lines specified by `chunkSize`. The sequences can then be identified by searching the database for the `identifier` provided. Sequences are added to the database verbatim, so that no sequence information is lost when the sequences are exported from the database. The sequence (record) names are recorded into a column named "description" in the database.

Value

The total number of sequences in the database table is returned after import.

Warning

If `replaceTbl` is TRUE then any sequences already in the table are overwritten, which is equivalent to dropping the entire table.

StaggerAlignment *Produce a Staggered Alignment*

Description

Staggers overlapping characters in a multiple sequence alignment that are better explained by multiple insertions than multiple deletions.

Usage

```
StaggerAlignment(myXStringSet,
                 tree = NULL,
                 threshold = 3,
                 fullLength = FALSE,
                 processors = 1,
                 verbose = TRUE)
```

Arguments

myXStringSet	An AAStringSet, DNASTringSet, or RNASTringSet object of aligned sequences.
tree	A bifurcating dendrogram representing the evolutionary relationships between sequences, such as that created by IdClusters . The root should be the topmost node of the tree.
threshold	Numeric giving the ratio of insertions to deletions that must be met to stagger a region of the alignment. Specifically, the number of insertions divided by deletions must be less than threshold to stagger.
fullLength	Logical specifying whether the sequences are full-length (TRUE), or terminal gaps should be treated as missing data (FALSE, the default). Either a single logical, a vector with one logical per sequence, or a list with <code>right</code> and <code>left</code> components containing logicals for the right and left sides of the alignment.
processors	The number of processors to use, or NULL to automatically detect and use all available processors.
verbose	Logical indicating whether to display progress.

Details

Multiple sequence aligners typically maximize true homologies at the expense of increased false homologies. `StaggerAlignment` creates a “staggered alignment” which separates regions of the alignment that are likely not homologous into separate regions. This re-balances the trade-off between true positives and false positives by decreasing the number of false homologies at the loss of some true homologies. The resulting alignment is less aesthetically pleasing because it is widened by the introduction of many gaps. However, in an evolutionary sense a staggered alignment is more correct because each aligned position represents a hypothesis about evolutionary events: overlapping characters between any two sequences represent positions common to their ancestor sequence that may have evolved through substitution.

The single parameter `threshold` controls the degree of staggering. Its value represents the ratio of insertions to deletions that must be crossed in order to stagger a region. A threshold of 1 would mean any region that could be better explained by separate insertions than deletions should be staggered. A higher value for `threshold` makes it more likely to stagger, and vice-versa. A very high value would conservatively stagger most regions with gaps, resulting in few false homologies but also fewer true homologies. The default value (3) is intended to remove more false homologies than it eliminates in true homologies. It may be preferable to tailor the threshold depending on the purpose of the alignment, as some downstream procedures (such as tree building) may be more or less sensitive to false homologies.

Value

An `XStringSet` of aligned sequences.

Synteny

Synteny blocks and hits

Description

Syntenic blocks are DNA segments composed of conserved hits occurring in the same order on two sequences. The two sequences are typically chromosomes of different species that are hypothesized to contain homology. Class `"Synteny"` provides objects and functions for storing and viewing syntenic blocks and hits that are shared between sequences.

Usage

```
## S3 method for class 'Synteny'
pairs(x,
      bounds = TRUE,
      boxBlocks = FALSE,
      labels = abbreviate(rownames(x), 9),
      gap = 0.5,
      line.main = 3,
      cex.labels = NULL,
      font.labels = 1,
      ...)

## S3 method for class 'Synteny'
plot(x,
     colorBy = 1,
     colorRamp = colorRampPalette(c("#FCF9EE", "#FFF272",
                                   "#FFAC28", "#EC5931",
                                   "#EC354D", "#0D0887")),

     barColor = "#CCCCCC",
     barSides = ifelse(nrow(x) < 100, TRUE, FALSE),
     horizontal = TRUE,
     labels = abbreviate(rownames(x), 9),
     cex.labels = NULL,
     width = 0.7,
     scaleBar = TRUE,
     ...)

## S3 method for class 'Synteny'
print(x,
      quote = FALSE,
      right = TRUE,
      ...)
```

Arguments

<code>x</code>	An object of class <code>Synteny</code> .
<code>bounds</code>	Logical specifying whether to plot sequence boundaries as horizontal or vertical lines.
<code>boxBlocks</code>	Logical indicating whether to draw a rectangle around hits belonging to the same block of synteny.
<code>colorBy</code>	Numeric giving the index of a reference sequence, or a character string indicating to color by “neighbor”, “frequency”, or “none”. (See details section below.)
<code>colorRamp</code>	A function that will return <code>n</code> colors when given a number <code>n</code> . Examples are <code>rainbow</code> , <code>heat.colors</code> , <code>terrain.colors</code> , <code>cm.colors</code> , or (the default) <code>colorRampPalette</code> .
<code>barColor</code>	Character string giving the background color of each bar.
<code>barSides</code>	Logical indicating whether to draw black lines along the long-sides of each bar.
<code>horizontal</code>	Logical indicating whether to plot the sequences horizontally (<code>TRUE</code>) or vertically (<code>FALSE</code>).
<code>labels</code>	Character vector providing names corresponding to each “identifier” for labels on the diagonal.

<code>width</code>	Numeric giving the fractional width of each bar between zero and one.
<code>scaleBar</code>	Logical controlling whether a scale bar is drawn when <code>colorBy</code> is “frequency”. The scale bar displays the mapping between color and the level of sequence conservation. Not applicable when <code>colorBy</code> is a value other than “frequency”.
<code>gap</code>	Distance between subplots, in margin lines.
<code>line.main</code>	If <code>main</code> is specified, <code>line.main</code> provides the <code>line</code> argument to <code>mtext</code> .
<code>cex.labels</code>	Magnification of the labels.
<code>font.labels</code>	Font of labels on the diagonal.
<code>quote</code>	Logical indicating whether to print the output surrounded by quotes.
<code>right</code>	Logical specifying whether to right align strings.
<code>...</code>	Other graphical parameters for <code>pairs</code> or <code>plot</code> , including: <code>main</code> , <code>cex.main</code> , <code>font.main</code> , and <code>oma</code> . Other arguments for <code>print</code> , including <code>print.gap</code> and <code>max</code> .

Details

Objects of class `Synteny` are stored as square matrices of list elements with `dimnames` giving the “identifier” of the corresponding sequences. The `synteny` matrix can be separated into three parts: along, above, and below the diagonal. Each list element along the diagonal contains an integer vector with the width of the sequence(s) belonging to that “identifier”. List elements above the diagonal (column $j >$ row i) each contain a matrix with “hits” corresponding to matches between sequences i and j . List elements below the diagonal each contain a matrix with “blocks” of synteny between sequences j and i .

The `pairs` method creates a scatterplot matrix from a `Synteny` object. Dot plots above the diagonal show hits between identifier i and j , where forward hits are colored in black, and hits to the reverse strand of identifier j are colored in red. Plots below the diagonal show blocks of synteny colored by their score, from green (highest scoring) to blue to magenta (lowest scoring).

The `plot` method displays a bar view of the sequences in the same order as the input object (`x`). The coloring scheme of each bar is determined by the `colorBy` argument, and the color palette is set by `colorRamp`. When `colorBy` is an index, the sequences are colored according to regions of shared homology with the specified reference sequence (by default 1). If `colorBy` is “neighbor” then shared syntenic blocks are connected between neighboring sequences. If `colorBy` is “frequency” then positions in each sequence are colored based on the degree of conservation with the other sequences. In each case, regions that have no correspondence in the other sequence(s) are colored `barColor`.

plot(synteny, "neighbor") # connect neighbors

```

Taxa

Taxa training and testing objects

Description

Taxonomic classification is the process of assigning an organism a label that is part of a taxonomic hierarchy (e.g., Phylum, Class, Order, Family, Genus). Here, labels are assigned based on an organism's DNA or RNA sequence at a rank level determined by the classification's confidence. Class Taxa provides objects and functions for storing and viewing training and testing objects used in taxonomic classification.

Usage

```

## S3 method for class 'Taxa'
plot(x,
     y = NULL,
     showRanks = TRUE,
     n = NULL,
     ...)

```

```
## S3 method for class 'Taxa'
print(x,
      ...)
```

Arguments

<code>x</code>	An object of class <code>Taxa</code> with subclass <code>Train</code> or <code>Test</code> .
<code>y</code>	An (optional) object of class <code>Taxa</code> with the opposite subclass as <code>x</code> .
<code>showRanks</code>	Logical specifying whether to show all rank levels when plotting an object of class <code>Taxa</code> and subclass <code>Test</code> . If <code>TRUE</code> (the default), then ranks are shown as (colored) concentric rings with radial lines delimiting taxa boundaries.
<code>n</code>	Numeric vector giving the frequency of each classification if <code>x</code> or <code>y</code> is an object of subclass <code>Test</code> , or the default (<code>NULL</code>) to treat all classifications as occurring once. Typically, specifying <code>n</code> is useful when the classifications represent varying numbers of observations, e.g., when only unique sequences were originally classified.
<code>...</code>	Other optional parameters.

Details

Objects of class `Taxa` are stored as lists, and can have either subclass `Train` or `Test`. The function `LearnTaxa` returns an object of subclass `Train`, while the function `IdTaxa` can return an object of class `Test`.

Training objects are built from a set of reference sequences with known taxonomic classifications. List elements contain information required by `IdTaxa` for assigning a classification to test sequences.

Testing objects can be generated by `IdTaxa` from a `Training` object and a set of test sequences. Each list element contains the taxon, confidence, and (optionally) rank name of the taxonomic assignment.

The information stored in `Taxa` can be visualized with the `plot` function or displayed with `print`. Only objects of subclass `Train` can be subsetted without losing their class.

TerminalChar	<i>Determine the Number of Terminal Characters</i>
--------------	--

Description

Counts the number of terminal characters for every sequence in an XStringSet. Terminal characters are defined as a specific character repeated at the beginning and end of a sequence.

Usage

```
TerminalChar(myXStringSet,  
            char = "")
```

Arguments

myXStringSet	An XStringSet object of sequences.
char	A single character giving the terminal character to count, or an empty character ("") indicating to count both gap ("-") and unknown (".") characters.

Value

A matrix containing the results for each sequence in its respective row. The first column contains the number of leading char, the second contains the number of trailing char, and the third contains the total number of characters in-between.

TileSeqs	<i>Form a Set of Tiles for Each Group of Sequences.</i>
----------	---

Description

Creates a set of tiles that represent each group of sequences in the database for downstream applications.

Usage

```
TileSeqs(dbFile,
         tblName = "Seqs",
         identifier = "",
         minLength = 26,
         maxLength = 27,
         maxTilePermutations = 10,
         minCoverage = 0.9,
         add2tbl = FALSE,
         processors = 1,
         verbose = TRUE,
         ...)
```

Arguments

dbFile	A SQLite connection object or a character string specifying the path to the database file.
tblName	Character string specifying the table of sequences to use for forming tiles.
identifier	Optional character string used to narrow the search results to those matching a specific identifier. If "" then all identifiers are selected.
minLength	Integer providing the minimum number of nucleotides in each tile. Typically the same or slightly less than maxLength.
maxLength	Integer providing the maximum number of nucleotides in each tile. Tiles are designed primarily for this length, which should ideally be slightly greater than the maximum length of oligos used in downstream functions.
maxTilePermutations	Integer specifying the maximum number of tiles in each target site.
minCoverage	Numeric providing the fraction of coverage that is desired for each target site in the group. For example, a minCoverage of 0.9 request that additional tiles are added until 90% of the group is represented by the tile permutations.
add2tbl	Logical or a character string specifying the table name in which to add the result.
processors	The number of processors to use, or NULL to automatically detect and use all available processors.
verbose	Logical indicating whether to display progress.
...	Additional arguments to be passed directly to SearchDB.

Details

TileSeqs will create a set of overlapping tiles representing each target site in an alignment of sequences. The most common tile permutations are added until the desired minimum group coverage is obtained. The dbFile is assumed to contain DNASTringSet sequences (any U's are converted to T's).

Target sites with one more more tiles not meeting a set of requirements are marked with `misprime` equals TRUE. Requirements include minimum group coverage, minimum length, and maximum length. Additionally, tiles are required not to contain more than four runs of a single base or four di-nucleotide repeats.

Value

A `data.frame` with a row for each tile, and multiple columns of information. The `row_names` column gives the row number. The `start`, `end`, `start_aligned`, and `end_aligned` columns provide positioning of the tile in a consensus sequence formed from the group. The column `misprime` is a logical specifying whether the tile meets the specified constraints. The columns `width` and `id` indicate the tile's length and group of origin, respectively.

The `coverage` field gives the fraction of sequences containing the tile in the group that encompass the tile's start and end positions in the alignment, whereas `groupCoverage` contains the fraction of all sequences in the group containing a tile at their respective target site. For example, if only a single sequence out of 10 has information (no gap) in the first alignment position, then `coverage` would be 100% (1.0), while `groupCoverage` would be 10% (0.1).

The final column, `target_site`, provides the sequence of the tile.

Note

If `add2tbl` is `TRUE` then the tiles will be added to the database table that currently contains the sequences used for tiling. The added tiles may cause interference when querying a table of sequences. Therefore, it is recommended to add the tiles to their own table, for example, by using `add2tbl="Tiles"`.

TrainingSet_16S

Training Set for Classification of 16S rRNA Gene Sequences

Description

A pre-trained classifier for 16S rRNA gene sequences generated by [LearnTaxa](#).

Usage

```
data("TrainingSet_16S")
```

Format

A training set of class 'Taxa' * K-mer size: 8 * Number of rank levels: 10 * Total number of sequences: 2472 * Number of taxonomic groups: 2472 * Number of problem groups: 5 * Number of problem sequences: 8

Details

The original training sequences were pruned to a maximum of one sequence per group, as described in the 'Classifying Sequences' vignette.

Note

This 16S rRNA training set is provided for illustrative purposes only. It is highly recommended to use a more comprehensive training set when classifying real sequences. Examples of comprehensive training sets can be found at <http://DECIPHER.codes/Download.html>.

Source

Derived from version 16 of the RDP Training Set (<http://rdp.cme.msu.edu>) based on Bergey's Manual.

TrimDNA

Trims DNA Sequences to the High Quality Region Between Patterns

Description

Aids in trimming DNA sequences to the high quality region between a set of patterns that are potentially present on the left and right sides.

Usage

```
TrimDNA(myDNAStringSet,
        leftPatterns,
        rightPatterns,
        type = "ranges",
        quality = NULL,
        maxDistance = 0.1,
        minOverlap = 5,
        allowInternal = TRUE,
        alpha = 0.1,
        threshold = 0.01,
        maxAverageError = threshold,
        maxAmbiguities = 0.1,
        minWidth = 36,
        verbose = TRUE)
```

Arguments

myDNAStrngSet	A DNAStrngSet object containing the sequences to be trimmed.
leftPatterns	A DNAStrngSet or character vector of patterns to remove from the left side of myDNAStrngSet, or "" to prevent trimming patterns on the left.
rightPatterns	A DNAStrngSet or character vector of patterns to remove from the right side of myDNAStrngSet, or "" to prevent trimming patterns on the right.
type	Character string indicating the type of results desired. This should be (an abbreviation of) either "ranges", "sequences" or "both".
quality	Either NULL (the default) to skip quality trimming, or a PhredQuality, SolexaQuality, or IlluminaQuality object containing the quality scores corresponding to myDNAStrngSet.
maxDistance	Numeric between zero and one giving the maximum distance of a match from the leftPatterns and rightPatterns to initiate trimming. For example, 0.1 (the default) would allow up to 10% mismatches between a pattern and sequence.
minOverlap	Integer specifying the minimum number of nucleotides the leftPatterns and rightPatterns must overlap a sequence to initiate trimming.
allowInternal	Logical initiating whether to search for the leftPatterns and rightPatterns within myDNAStrngSet, or (FALSE for) only overlapping the ends.
alpha	Numeric between zero and one giving the smoothing parameter for an exponential moving average that is applied to the quality scores before trimming. Higher values result in less smoothing than lower values.
threshold	Numeric between zero and one specifying the threshold above which to trim the poor quality regions of the sequence. Higher values allow more sequence to be preserved at the expense of a greater error rate.
maxAverageError	Numeric between zero and threshold indicating the maximum average error rate of the trimmed region of the sequence. Trimmed sequences with average error rates above maxAverageError will be rejected. Note that the expected number of errors in a sequence is equal to the average error rate multiplied by the length of the sequence.
maxAmbiguities	Numeric between zero and one giving the maximum fraction of ambiguous (e.g., "N") positions that are tolerated within the trimmed region of the sequence. Trimmed sequences with a greater fraction of ambiguities than maxAmbiguities will be rejected.
minWidth	Integer giving the minimum number of nucleotides a pattern must overlap the sequence to initiate trimming.
verbose	Logical indicating whether to display progress.

Details

After a sequencing run, it is often necessary to trim the resulting sequences to the high quality region located between a set of patterns. TrimDNA works as follows: first left and right patterns are identified within the sequences if allowInternal is TRUE (the default). If the patterns are not found internally, then a search is conducted at the flanking ends for patterns that partially overlap the sequence. The region between the leftPatterns and rightPatterns is then returned, unless quality information is provided.

If quality contains quality scores, these are converted to error probabilities and an exponential moving average is applied to smooth the signal. The longest region between the leftPatterns

and rightPatterns where the average error probability is below threshold is then returned, so long as it has an average error rate of at most maxAverageError. Note that it is possible to only filter by maxAverageError by setting threshold to 1, or vice-versa by setting maxAverageError to threshold.

Value

TrimDNA can return two types of results: IRanges that can be used for trimming myDNAStrngSet, or a trimmed DNAStrngSet containing only those sequences over minWidth nucleotides after trimming. Note that ambiguity codes (IUPAC_CODE_MAP) are supported in the leftPatterns and rightPatterns, but not in myDNAStrngSet to prevent trivial matches (e.g., runs of N's).

If type is "ranges" (the default) the output is an IRanges object with the start, end, and width of every sequence. This information can be accessed with the corresponding accessor function (see examples below). Note that the start will be 1 and the end will be 0 for sequences that were not at least minWidth nucleotides after trimming.

If type is "sequences" then the trimmed sequences are returned that are at least minWidth nucleotides in length.

If type is "both" the output is a list of two components, the first containing the ranges and the second containing the sequences.

WriteDendrogram

Write a Dendrogram to Newick Format

Description

Writes a dendrogram object to a file in Newick (also known as New Hampshire) parenthetic format.

Usage

```
WriteDendrogram(x,
                file = "",
                quoteLabels = TRUE,
                convertBlanks = !quoteLabels,
                internalLabels = TRUE,
                digits = 10,
                append = FALSE)
```

Arguments

x	An object of class dendrogram.
file	A connection or a character string naming the file path where the tree should be exported. If "" (the default), the tree is printed to the standard output connection, the console unless redirected by sink.
quoteLabels	Logical specifying whether to place leaf labels in double quotes.
convertBlanks	Logical specifying whether to convert spaces in leaf labels to underscores.
internalLabels	Logical indicating whether to write any “edgetext” preceding a node as an internal node label.
digits	The maximum number of digits to print for edge lengths.
append	Logical indicating whether to append to an existing file. Only applicable if file is a character string. If FALSE (the default), then the file is overwritten.

Details

WriteDendrogram will write a dendrogram object to a file in standard Newick format. Note that special characters (commas, square brackets, colons, semi-colons, and parentheses) present in leaf labels will likely cause a broken Newick file unless quoteLabels is TRUE (the default).

Value

NULL.
